

## The Role of People versus Places in Individual Carbon Emissions<sup>†</sup>

By EVA LYUBICH\*

*There is substantial spatial heterogeneity in household carbon emissions. I leverage movers in two decades of administrative Decennial Census and American Community Survey data to estimate place effects—the amount by which carbon emissions change for the same household living in different places—for almost 1,000 cities and roughly 61,500 neighborhoods across the United States. I estimate that place effects account for 14–23 percent of overall heterogeneity. A change in neighborhood-level place effects from 1 standard deviation above the mean to 1 below would reduce household carbon emissions from residential energy and commuting by about 40 percent. (JEL D12, D15, L94, Q41, Q54, R11, R23)*

Increased carbon and other greenhouse gas emissions since the onset of the industrial revolution have caused global average temperatures to rise by over 1°C (1.8°F) relative to preindustrial levels (NASA 2020). In 2015, the United States signed the Paris Accord, a global agreement aimed at mitigating the potential damages from climate change by limiting overall warming to below 2°C. In search of opportunities for decarbonization, researchers and policymakers have pointed to substantial spatial heterogeneity in household carbon emissions, suggesting that perhaps higher-emissions places could adopt features of lower-emissions places, such as density and high-quality public transportation infrastructure, in order to lower household carbon emissions (e.g., Jones and Kammen 2014; International Energy Agency 2021; Pomponi et al. 2021; Wagner 2021).

However, differences in mean carbon emissions across places reflect a combination of local amenities, household characteristics, and taste-based sorting. The relative contributions of these pieces is a central determinant of whether place-based interventions that change urban form would lead to significant reductions in carbon emissions. For instance, if places with large single-family homes and car-oriented transportation infrastructure are high-emissions because the people who live there dislike multifamily homes and public transit, then deregulating zoning or building new rail lines would have little impact on household emissions. Conversely, if the lack of denser housing and transit options is a constraint on household choices, rather than a reflection of their preferences, then interventions that change these local public amenities have the potential to decrease carbon emissions for many households at once.

In this paper, I decompose variation in household carbon emissions into a component driven by household characteristics and a component driven by place effects, that is, the amount by which the same household's carbon emissions would differ from place to place due to differences in the underlying features of those places. To do so, I construct a longitudinal panel of residential and transportation energy use for over 1 million individuals from 20 years of restricted-access Decennial Census and American Community Survey (ACS) (US Census Bureau 2000, 2010, 2001–2019). The longitudinal nature of these data allows me to link individual survey respondents over time and across places. I use a mover design, examining changes to household carbon emissions for over 250,000 movers across roughly 1,000 cities and 61,500 neighborhoods, to estimate place effects and their contribution to heterogeneity in carbon emissions.

I begin my analysis by documenting observational patterns of city- and neighborhood-level variation in household carbon emissions in my sample. While previous work has shown evidence of substantial variation in household carbon emissions (e.g., Jones and Kammen 2014; Ummel 2014; Green and Knittel 2020), the level of geographic granularity in publicly available data has limited researchers to predicting neighborhood-level carbon emissions from national data projected onto local place and household characteristics. In contrast, detailed geographic identifiers in the administrative Census Bureau microdata make it possible to directly estimate neighborhood-level means. I estimate that on average, households living in cities with emissions 1 standard deviation above the mean emit 50 percent more than those living in cities 1 standard deviation below the mean. Similarly, households in neighborhoods 1 standard deviation above the mean emit, on average, just under twice as much as those in neighborhoods 1 standard deviation below the mean. Accounting for variation driven by observed household characteristics such as household size and income decreases the dispersion across place estimates by less than 10 percent.

The heterogeneity that remains after accounting for observable household characteristics reflects some combination of unobserved household characteristics and causal place effects. Unobserved household characteristics might include preferences for spending time in a private yard versus a public park, risk tolerances for biking versus driving, sensitivities to hot or cold temperatures, or simply environmental consciousness. Place effects could stem from a variety of local amenities and supply-side factors that determine patterns of household energy use. They could reflect aspects of urban form such as public transportation, bike and pedestrian infrastructure, highway networks, density, or zoning regulations. They could

also be driven by natural amenities such as climate. Lastly, they could arise from supply-side factors that determine fuel shares and electricity emissions factors, both of which shift the amount of carbon emitted for a given level of energy use.<sup>1</sup> I show how place effects can be interpreted through the lens of a consumer energy demand model in which average energy demand, energy demand elasticities, energy prices, and average emissions factors vary across places.

My empirical strategy uses movers to estimate the contributions of place effects and household characteristics to heterogeneity in household carbon emissions. The mover design accounts for unobserved differences between households by comparing carbon emissions for the same household living in different places. Consider the following thought experiment. Imagine two households identical in every observable way—same household size, same income, same education levels, etc. One lives in a dense, urban neighborhood well-served by public transit, while the other lives in a car-dependent suburb with large homes. The urban household likely generates lower carbon emissions. But is that because the place itself determines emissions or because the urban household has different unobservable characteristics, like stronger environmental preferences, that led it to select into the lower emissions neighborhood? If I observe the same household move between neighborhoods, any resulting change in that household's emissions can no longer be attributed to fixed unobserved household preferences or characteristics, and I can use those changes to infer differences in place effects. In order for estimates from the mover design to be unbiased, the central assumption is that mover destinations are uncorrelated with changes to unobserved determinants of household carbon emissions. A crucial advantage of undertaking this analysis with Census Bureau microdata is that I observe, and can control for, many time-varying household characteristics that could correlate with both potential emissions and destination choices and thereby confound estimates of place effects. In other words, the identifying strategy does not allow for households to move in response to a sudden shift in environmental preferences, but it does allow for households to move in response to changes in income, the number of children, and age-based or life cycle preferences, because I observe these characteristics.

For the first set of results, I use an event study to estimate how much carbon emissions change after households move, as a share of the mean difference between their origin and destination. Intuitively, if spatial heterogeneity is driven in part by underlying differences between places, when a household moves, I should see its emissions shift toward the mean of its new location. The larger the shift, the more important the role of place. I find that, on average, when households move to a new city, their carbon emissions change by about 85 percent of the mean difference between origin and destination cities. Sorting plays a larger role in neighborhood-level variation than in variation across cities, but the role of place remains meaningful; when households move to a new neighborhood, their carbon emissions change by 53–60 percent of the mean difference between their origin and destination neighborhoods.

<sup>1</sup>For instance, a household in an area with predominantly coal-fired power plants could emit significantly more carbon than a household with identical electricity consumption in an area powered mainly by natural gas or renewable sources. Similarly, many households in the Northeast use heating oil, in part due to legacy equipment choices, which produces substantially more carbon dioxide for the same amount of heating than natural gas.

I explore several dimensions of heterogeneity, finding that my estimates remain stable when restricting the sample to households without significant changes in observable characteristics, when splitting the sample by duration between observations, and when grouping movers based on the magnitude of origin-destination differences in observational mean emissions. The consistency of estimates across these analyses suggests limited systematic sorting of households to places, as such sorting would manifest in a nonlinear relationship between observational means and household emissions. In the absence of systematic sorting, the event study estimates can be interpreted as causal estimates of the effect on emissions of any household moving between any pair of places. While the heterogeneity analysis lends support to this interpretation, the additional assumption of no systematic sorting is quite strong, particularly at the neighborhood level. Under the weaker baseline assumptions, the event study estimates yield unbiased predictions about how household carbon emissions change for any set of observed moves. This is valuable, as it makes it possible to calculate the carbon emissions externality of policies or regulatory restrictions that drive existing patterns of household migration, for instance, policies that restrict housing supply in on average lower-emissions cities.

In the second set of results, I estimate the full nonparametric distribution of household and place effects using a two-way fixed effects model and then do a variance decomposition to estimate the share of overall heterogeneity explained by each component. This approach allows for unrestricted patterns of sorting, but this weaker assumption comes at the cost of limited mobility bias (Andrews et al. 2008): Estimates of place effects are noisy because they can be derived from a small number of movers to and from each place. This imprecision creates an upward bias in the naïve plug-in variance estimate relative to the true variance of place effects, even if estimates of place effects themselves are unbiased. I account for this upward bias using the heteroskedasticity-robust “leave-out” estimator proposed by Kline, Saggio, and Sølvesten (2020). I find low correlations between unobserved household and place effects, even at the neighborhood level. This suggests that sorting on unobserved household characteristics contributes to differences between places through “segregation” of households, but not in a way that is systematically correlated with unobserved neighborhood attributes. City effects explain 14–16 percent of overall heterogeneity, while neighborhood effects explain roughly 22–23 percent of overall heterogeneity. Climate, electricity emissions factors, and energy prices together account for over half of the core-based statistical area (CBSA) variance component. At the neighborhood level, controlling for these factors decreases the place share by less than half, to about 15 percent. While this leaves the majority of overall heterogeneity to other factors, my estimates nevertheless imply the potential for considerable reductions to household carbon emissions from interventions that decrease place effects: I estimate that if a neighborhood went from having a place effect 1 standard deviation above the national mean to having a place effect 1 standard deviation below the national mean, household emissions for residents of that neighborhood would decrease by about 40 percent.

I characterize low- and high-emissions neighborhoods by presenting correlations between estimated tract effects and observable tract-level characteristics. I characterize local amenities using observable characteristics from within the Census Bureau microdata; public-use data on climate and electricity; and commercial data

from Walk Score, a private company that generates estimates of the walkability, transitability, and bikeability of every address in the United States (Walk Score 2021). These data lend unique insight into highly granular variation in neighborhood characteristics. I find that the correlations between amenities and neighborhood place effects for the most part mirror the relationships in the observational data. Low-emissions places have clean electricity and mild climates, and they have amenities characteristic of urban areas. Among the local amenities, density and average home size, proximity to principal cities, and the quality of local bike infrastructure appear to have the most explanatory power.

I conclude my analysis by examining how household carbon emissions would differ if some households were exposed to the place effects of neighborhoods more urban than the one they currently live in. If suburban and rural households lived in a place with the average place effect of the principal city closest to them—a scenario that captures in spirit how households’ exposure to place effects might shift in response to regulations that limit urban sprawl and encourage upzoning and infill development—I estimate that their emissions from residential energy use and commuting would decrease by about 15 percent. To put this estimate into context, the Inflation Reduction Act (IRA), which was signed into law in August 2022 and is the largest federal effort to address climate change to date, is projected to decrease economy-wide emissions in 2030 by an additional 15 percent relative to projected reductions from 2005 levels under business as usual.<sup>2</sup>

In many ways, the basic physical design and urban fabric of cities, suburbs, and towns creates the foundational patterns of transportation and residential energy use. Decades of housing, transportation, and land use policies shape these features. The wide distribution of place effects estimated in this paper implies that there may be potential for “place-based climate policies”—policies that aim to reduce household carbon emissions from residential and transportation energy by changing the underlying characteristics of the places people live in—to lead to meaningful reductions in carbon emissions. While this paper does not estimate the causal drivers of place effects, the correlational analysis presented here and many observational and model-based studies (e.g., Shammin et al. 2010; Timmons, Ziogiannis, and Lutz 2016; Ribeiro, Rybski, and Kropp 2019; Pomponi et al. 2021; Ko 2013) provide some hypotheses. Estimating causal relationships between specific amenities and place effects using credible exogenous variation remains an important direction for future research. One might have worried about whether the settings in which such studies can be done are too selected; what if the households that reside in places that make changes to local infrastructure or regulatory restrictions are different from households in places that do not make those changes? The core results of this paper suggest that variation in place effects drives a meaningful share of differences in emissions between places, mitigating some of these concerns about external validity.

<sup>2</sup>Three separate efforts to model IRA reductions have been commonly cited by advocates and lawmakers. The Rhodium Group estimates that under the IRA, emissions will fall 31–44 percent from 2005 levels by 2030, with 24–34 percent reductions under business as usual (Larsen et al. 2022). For the same time frame, Energy Innovation estimates 37–41 percent reductions under the IRA and 24 percent under business as usual (Mahajan et al. 2022), and the REPEAT project estimates 42 percent reductions under the IRA and 17 percent under business as usual (Jenkins et al. 2022).

This paper makes several contributions. A large body of work in labor and urban economics finds significant wage, employment, and productivity benefits from density and integrated land use and transit policies (Tsivanidis 2022; Allen and Arkolakis 2022; Duranton and Puga 2020). These studies suggest that spatial equilibria are inefficient due to agglomeration economies and other externalities but have largely not considered the carbon emissions externality in their analysis. The theoretical justification for using place-based policies in cases where agglomeration economies and other local externalities exist is well-established. Federal intervention can correct inefficient market equilibria and improve welfare by supplementing local government provision of underprovided amenities, offering a “big push” toward an optimal equilibrium when several exist, fostering the growth of productive areas and agglomeration externalities or insuring residents against place-based shocks (Glaeser and Gottlieb 2008; Kline 2010; Kline and Moretti 2014; Glaeser 2013; Austin, Glaeser, and Summers 2018). However, the empirical evidence on the efficacy of place-based policies is mixed. While some studies find that tax incentives targeting areas with lower employment can improve welfare (Busso, Gregory, and Kline 2013; Austin, Glaeser, and Summers 2018; Bilal 2023), others suggest that spatial policies promoting growth in less developed areas may have negligible or even negative aggregate effects on productivity and welfare (Kline and Moretti 2013; Gaubert 2018). Duranton and Venebles (2021) highlight the challenges in evaluating place-based policies, including in the context of urban transport, housing, and infrastructure. The welfare implications of place-based climate policies would crucially depend on their design, implementation details, costs, and household preferences for local amenities; a welfare analysis is beyond the scope of this paper. Carbon emissions are a canonical example of a global externality, but many of the theoretical justifications for place-based policy outlined above could be relevant, given the observed relationship between carbon emissions and factors of urban form, such as density and urban transport. This, together with evidence from this paper that places play an important role in driving household carbon emissions, suggests that further research is warranted.

Methodologically, I build on a large literature in labor examining wage inequality across firms and a growing literature that uses mover designs to estimate place effects on other individual outcomes, e.g., nutritional choices (Allcott et al. 2019), health outcomes and health care utilization (Eid et al. 2008; Finkelstein, Gentzkow, and Williams 2016, 2021), intergenerational mobility (Chetty and Hendren 2018), and wages (De la Roca and Puga 2017; Card, Rothstein, and Yi 2025). This paper is the first to use a mover design to study household energy use and carbon emissions, yielding new insights into spatial heterogeneity in these outcomes. Previous work has highlighted the consequences of spatial heterogeneity in carbon emissions for allocative efficiency (Glaeser and Kahn 2010; Colas and Morehouse 2022) as well as for distributional impacts and the political economy of hypothetical climate policies (Cronin, Fullerton, and Sexton 2019; Sallee 2019; Green and Knittel 2020), but these papers did not examine the causal role of places in their findings. Several papers in the literature have generated estimates of heterogeneous energy demand parameters, but they have necessarily done so in spatially limited and sector-specific contexts (Auffhammer and Rubin 2024; Gillingham 2014; Nowak and Savage 2013; Spiller et al. 2014). The estimates generated in this paper on the relative roles of

place effects versus household sorting could assist in resolving some of the challenges identified in the aforementioned literature around distributional impacts and political economy. For instance, if lock-in of urban form limits the share of household carbon emissions that could be targeted by pricing instruments in the short-to-medium term, estimates of the share of spatial heterogeneity driven by place effects could inform decisions around how much to redistribute carbon dividends when using geography as a tag. And as highlighted previously, they raise an important question as to whether place-based climate policies could serve as a welfare-improving complement to traditional instruments for addressing this global externality.

## I. Data and Stylized Facts about Carbon Emissions in the United States

Seventy-five percent of US greenhouse gas emissions are from burning fossil fuels. Of these, 20 percent are from residential energy use (including electricity), and another 20 percent are from light-duty (i.e., passenger) vehicles (US Energy Information Administration 2020b). The focus of this analysis is on carbon emissions from these two sectors; they are a meaningful portion of overall emissions, and they are the forms of emissions that are most directly related to locked-in characteristics of urban form. In the remainder of this section, I first discuss my data and the construction of relevant analysis variables and then provide some descriptive evidence on heterogeneity in carbon emissions in my sample.

### A. Data and Key Variables

I build a 20-year panel of individual and household-level data using the 2000 restricted-access Decennial Census long form and the 2001–2019 American Community Survey (US Census Bureau 2000, 2010; 2001–2019). The 2000 Decennial Census long form consists of a stratified random sample covering one in six households in the United States. After 2000, the ACS replaced the Decennial Census long form in order to gather detailed information on individuals and households more regularly. The ACS is a stratified random sample covering roughly 0.4 percent of households in 2001–2005 and roughly 1 percent of households in each year after 2005 (US Census Bureau 2014). I link individuals across surveys using protected identification keys, which are unique person identifiers assigned by the US Census Bureau based on names, addresses, dates of birth, other household members, and social security numbers (when available).<sup>3</sup>

For every individual in the panel, I observe measures of residential and transportation energy use and a rich set of demographic, household, workplace, and home characteristics, including detailed geographic identifiers. I supplement the

<sup>3</sup>Neither the Decennial Census nor the ACS asks respondents for their social security numbers. Wagner and Layne (2014) use data with social security numbers to show that the error rate in assigning protected identification keys without social security numbers is below 1 percent. See Bond et al. (2014) for detailed discussion of the assignment algorithm used by the US Census Bureau. Assignment success rates vary across demographic groups—in particular, White and higher-income individuals are more likely to be successfully assigned a protected identification key—but for all demographic subgroups, the success rate is greater than 85 percent. See Bond et al. (2014) for additional discussion of the variation in assignment rates across population subgroups.

Decennial Census and ACS with several external sources of data in order to convert energy expenditures to energy services and emissions, and to characterize places.

*Geographic Units of Analysis.*—Throughout the study, I analyze spatial heterogeneity at two levels of geographic granularity that roughly represent a city or labor market and a neighborhood.

My first geographic unit of analysis is a core-based statistical area. CBSAs are designated by the Office of Management and Budget and cover the population of metropolitan and micropolitan areas in the United States. Each CBSA is a set of contiguous counties with strong commuting ties and at least one urban core area of at least 10,000 people. In addition to formally designated CBSAs, I define state-level residual CBSAs from unassigned rural areas. My second geographic unit of analysis is a census tract. Census tracts are county subdivisions that typically cover contiguous areas, have populations of 1,200–8,000 people (4,000 on average), and are delineated with boundaries that follow identifiable physical features. They are designed to be relatively stable but are split or merged every 10 years if populations exceed or fall below the 1,200–8,000 window.<sup>4</sup>

*Carbon Emissions.*—My primary outcome is metric tons of carbon emissions from residential energy and passenger vehicle use, which together account for roughly one-third of US greenhouse gas emissions. I implement the main analysis at the household level: Carbon emissions are given by household residential emissions plus the sum of individual commuting emissions over all individuals in the household.

I estimate carbon emissions from residential energy use from household-reported expenditures on electricity, natural gas, and other home heating fuels in the last year, combined with external data on local annual retail prices and fuel emissions factors. For electricity, I calculate county-level average prices using data from the Annual Electric Power Industry Report (US EIA 2020a). This report contains sales, revenues, and total customers for every major utility in the United States, by sector and state. It also delineates counties contained in each utility's service territory. I calculate county-level retail electricity prices using customer-weighted average prices (revenue divided by sales) across all utilities with service territories containing the county, and I compute household electricity consumption by dividing reported expenditures by my price estimates. I then assign households to one of 12 National Electric Reliability Council (NERC) regions using a tract-level crosswalk from the the Infrastructure Foundation-Level Database (US DHS 2021), and compute emissions using the average annual emissions rates assigned to each region by the Emissions and Generation Resource Integrated Database (US EPA 2021). For natural gas and other home heating fuels, I obtain average retail prices at the state level from the State Energy Data System (US EIA 1960-2019). If a household reports nonzero expenditures on "other home heating fuels," I impute the fuel used

<sup>4</sup>Census geographic definitions vary over time to account for changes in administrative boundaries and populations. To ensure that I don't erroneously identify people who live in places where the designation changed as movers, I use the 2000–2010 census block concordance to assign 2010 geographic definitions to all years in the data, combining blocks in cases where they correspond to a single 2000 block.

from its answer to the question, “What was the primary fuel used for home heating?” Finally, I obtain fuel emissions factors from the Emission Factors for Greenhouse Gas Inventories (US EPA 2018).

I estimate carbon emissions from transportation energy from the sum of individually reported commuting behavior within a household.<sup>5</sup> I estimate commute distance using the geodesic distance between home and place of work census blocks, and I estimated commute speed from estimated mileage and reported time length of commute. I estimate gasoline usage using annual national average fuel economy from the Bureau of Transportation Statistics (2000–2019) accounting for the fact that in general, fuel economy is roughly 30 percent higher on highways than in cities. Finally, I estimate the number of annual commutes using reported weeks worked last year and hours worked last week and convert annual gallons of gasoline to carbon emissions using the motor gasoline emissions factor from the State Energy Data System (US EIA 1960–2019). Individuals who commute by rail, subway, streetcar, bus, bike, or walk and individuals who work from home are assigned an emissions factor based on their mode of transit and data from the National Transit Database (Federal Transit Administration 2002–2019) (see Supplemental Appendix for more details). Altogether, this portion of the outcome captures variation in carbon emissions driven by commute lengths, number of commutes, and mode of transit. I examine the sensitivity of my results to using the National Household Travel Survey (NHTS, Federal Highway Administration 2022) to predict heterogeneous fuel economy and noncommute miles from household and geographic characteristics available in both the census and NHTS. This is not my baseline approach, as it infers how much of variation in vehicle fleets and fuel economy observed in the NHTS is driven by individual preferences versus place-based factors from cross-sectional variation.<sup>6</sup>

*Individual and Household Characteristics.*—Throughout the analysis, I use demographic and household characteristics to control for variation driven by observable characteristics. Specifically, I control for age, education (completion of a bachelor’s degree), sex, race and ethnicity, household income (from salaries and wages, interest, social security, supplemental security, public assistance, retirement, and self-employment), household size, number of children, and homeowner status. I aggregate individual-level demographics to the household level by taking the mean across individuals within a household.

I also observe whether a household lives in a detached single-family home, the number of rooms in a home, and the number of vehicles in the household. These characteristics are intermediate outcomes, which directly affect carbon emissions. They also very likely reflect a combination of household preferences and place characteristics; many places impose restrictions on multiunit homes and/or minimum lot sizes and lack transportation options for households without a car, so household choices

<sup>5</sup> Commuting accounts for about 28 percent of all vehicle-miles traveled and 39 percent of person-miles traveled on transit systems (US Department of Transportation 2015), which means I underestimate carbon emissions from overall personal vehicle use for most people in my sample.

<sup>6</sup> Place-based factors that contribute to variation in vehicle fleets could include social norms, perceptions of safety (e.g., if everyone around you is driving a big car, it is safer for you to drive a big car; certain types of cars may be able to handle adverse weather better), road widths, ease of parking, etc.

are likely to differ from place to place depending on these constraints. Therefore, I do not treat these variables as observable household characteristics when estimating place and household effects, but I do use them later to explore correlates of unobserved place and household heterogeneity.

It is not obvious whether homeownership should be considered an observable household characteristic or part of a place effect. Homeownership rates vary dramatically across CBSAs (Raetz 2021; Mateyka and Mazur 2021), and housing regulations can price people out of homeownership. In these cases, treating homeownership as an intermediate outcome seems appropriate. On the other hand, the choice to become a homeowner simultaneously impacts where people live and factors related to their carbon emissions. For instance, homeowners may want extra space for potential family expansion or space-intensive leisure activities or may choose homeownership in order to be able to install solar panels and have a place to charge their electric vehicle. To be conservative and err on the side of finding a smaller role of place effects, I treat homeowner status as an observable household characteristic in my baseline analysis.

*Place Characteristics and Amenities.*—I supplement Census Bureau microdata with several external sources of data to characterize amenities at the block, tract, city, and regional level. I focus on amenities that are directly relevant to energy consumption and carbon emissions in the residential and transportation sectors.

To capture variation in climate, I use data on annual heating degree days (HDDs) and cooling degree days (CDDs) at the CONUS Climate Division level (National Oceanic and Atmospheric Administration 2020). The National Oceanic and Atmospheric Administration (NOAA) divides the contiguous states into a total of 344 climate divisions based on regional differences in climates within states. Degree days represent the annual sum of the daily difference between that day's temperature and 65°F and are meant to quantify the heating and cooling requirements of a place.

To account for neighborhood-level variation in transportation and leisure amenities, I use data from Walk Score, a private company that generates estimates of the walkability, transitability, and bikeability of every address in the United States (Walk Score 2021).<sup>7</sup> Walk Score rankings capture proximity to different commercial amenities, such as grocery stores, as well as street characteristics, such as block lengths and intersection widths. Bike Score indexes capture characteristics that make biking more or less accessible, such as the existence of bike lanes, road connectivity, and hilliness. Transit Score ratings capture proximity to different types of transit and the frequency and connectivity of nearby options. For transit, I also observe the number of bus routes and rail routes within one-half mile. Other than route counts, each score is an index from 0–100. I assign over 6 million unique walk score points reflecting data from late 2020 through through early 2021, one to every populated census block in the United States, by matching census block centroids to the nearest walk score latitude-longitude coordinate.

<sup>7</sup>Data can be viewed at [www.walkscore.com](http://www.walkscore.com) and were provided by Redfin Real Estate ([www.redfin.com](http://www.redfin.com)).

Finally, I estimate density at the tract level using 2010 census block-level information on area and population. I define urban tracts as those that are characterized as urban by the US Census Bureau *and* surpass the density threshold set for urban centers by the EU-OECD definition of a functional urban area (Dijkstra, Poelman, and Veneri 2019).<sup>8</sup> I define suburban tracts as those contained within a CBSA but not designated as urban. Tracts outside of CBSAs are classified rural.

*Sample Restrictions.*—I restrict the analysis to individuals who are at least 18 years of age, who are not identified as the householder’s child or grandchild, and who are not missing any of the outcome variables or key explanatory or control variables described above. I also impose several additional restrictions related to energy variables. I exclude from the sample households for which residential energy costs are included in rent or gas costs are included in electricity bills because I don’t observe expenditures in those cases. I discuss this subsample of households and the potential impact of its exclusion in detail in the Supplemental Appendix. I also exclude individuals in households in which residential energy use is top-coded or whose commute time is top-coded, as the top-coding will obfuscate changes in individual consumption for the highest-demand individuals. Lastly, I exclude individuals if the sum of their household residential energy expenditures is 0, if they are in the bottom 1 percent of nonzero residential energy cost observations, or if they are in the top 1 percent of commute distance observations, as these outliers more likely reflect survey misreporting. My full sample consists of all individuals who meet these restrictions across the 48 continental states and the District of Columbia—almost 17 million people across over 12 million households (Table 1, column 1). I use the full sample to estimate observational geographic and household heterogeneity.

I construct a panel sample by restricting the full sample to individuals for whom I have at least two observations in which they did not indicate that they had moved within the last year. This restriction on very recent migration ensures that I am estimating household carbon emissions at the correct location, as households report their residential energy expenditures over the past year.<sup>9</sup> The panel sample consists of 1,097,000 people across 916,000 households (Table 1, column 2).

Finally, I impose two additional sample restrictions, which are necessary for the implementation of my empirical strategy. First, because residential energy is determined at the household level and place effects are identified from the variation in outcomes of movers between places, I restrict the panel sample to only households consisting of the same full-sample individuals across observations. This ensures that changes in emissions across observations are not driven by changes in the composition of adults in the household. Importantly, this approach does retain households where children are born or grow up and move out between observations, as individuals under 18 are not part of the full sample. Second, I restrict CBSAs and tracts to the “leave-out connected set”—the network of CBSAs or tracts that remain connected to each other by at least one mover after I drop all the observations of

<sup>8</sup>This threshold is 1,500 people per square kilometer.

<sup>9</sup>This restriction applies to all ACS years. The 2000 Decennial Census asked whether respondents had moved within the last five years. Since this is significantly more restrictive, I don’t drop these individuals.

TABLE 1—SAMPLE STATISTICS

		Panel sample			Mover sample	
	Full	All	CBSA	Tract	CBSA	Tract
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Panel A. Demographics</i>

<i>N</i> households	12,600,000	916,000	860,000	833,000	93,000	248,000
CBSAs	1,000	1,000	1,000	1,000	1,000	1,000
Tracts	71,500	70,000	70,000	61,500	54,500	61,500

*Notes:* Column 1 shows statistics for the full sample. Column 2 shows statistics for the panel sample, with no restrictions that individuals be in the same household or live in a connected geography. Columns 3 and 4 show the panel samples restricted to individuals in a consistent household over time and the CBSA and tract leave-one-out connected sets, respectively. Columns 5 and 6 show statistics for the CBSA and tract mover samples. All sample statistics are weighted using Census Bureau sample weights. Sample counts are unweighted and rounded according to Census Bureau disclosure rules.

any given household (see the Supplemental Appendix for an illustration). I do this after dropping tracts with fewer than 10 full-sample household observations. The leave-out connected sets are constructed separately at the CBSA and tract levels. This means it is possible for a household to be in the CBSA panel but not the tract panel. The leave-out restriction drops a negligible share of (residual) CBSAs and roughly 12 percent of (disproportionately rural) tracts, yielding approximately a 5 percent reduction in the number of households in the sample (Table 1, columns 3 and 4).

CBSA movers are households in the CBSA panel that live in different CBSAs across observations (93,000 households, column 5), and similarly, tract movers are households in the tract panel that live in different tracts (within or across CBSAs)

across observations (248,000 households, column 6). The CBSA panel, tract panel, CBSA movers, and tract movers make up my four primary analysis samples.

### B. Sample Statistics

Table 1 shows sample statistics for the full sample, unrestricted panel sample, the two geographically restricted panel samples, and the two mover samples.

A comparison across the samples yields three main takeaways. First, households in the panel are on average more likely to be White, have higher income, and are more likely to be homeowners than households in the full sample (columns 1 and 2). This reflects known heterogeneity in protected identification key assignment rates within the Census Bureau (Bond et al. 2014). The panel sample is also 7 percentage points less likely to live in an urban tract, 9 percentage points more likely to live in a detached home, and 2 percentage points more likely to commute by car. The appreciable drop in Transit Score when going from the full sample to the panel is consistent with these differences in urbanity and is likely in part driven by disproportionately dropping households in the densest areas when dropping households whose electricity and/or heating is included in rent, as discussed earlier and also in the Supplemental Appendix. Second, further restricting the baseline panel to the CBSA and tract panels (columns 3 and 4) does not meaningfully change the distribution of demographics, (intermediate) outcomes, or place characteristics. Finally, movers (columns 5 and 6) tend to be younger, more college educated, and have higher income than both stayers and the full sample. Movers also are more likely than stayers to live in urban tracts, less likely than stayers to live in detached homes, and they have higher rates of electric heating and lower emissions from residential energy, making them more comparable to the full sample on all of these dimensions.

Overall, a little under 80 percent of household carbon emissions in my sample are from residential energy, and a little over 20 percent are from commuting.<sup>10</sup> Close to three-quarters of the sample live in a detached, single-family home, a vast majority of the sample commutes by car, and on average, households live within half a mile of only 1 bus route and only 0.1 rail routes.

Table 2 shows additional statistics for the panel samples. I observe the vast majority of households in the panel sample exactly twice, with on average 8–10 years in between observations. Movers tend to be younger than stayers the first time I observe them and are much more likely to have had a child, experience a large change in real household income<sup>11</sup>, or transition from renting to owning their home. Households tend to move to places with higher shares of detached single-family homes and worse non-car transportation amenities. The majority of moves are from urban to urban tracts, urban to suburban tracts, or suburban to suburban tracts. Finally, consistent with secular trends of mobility in the United States, households generally move to

<sup>10</sup>Household carbon emissions from residential and transportation energy are roughly evenly split (US Energy Information Administration 2020b). Given that commuting makes up about 30 percent of transportation energy emissions, we would expect a slightly higher than 3:1 ratio of residential to commuting energy. My estimates appear to overstate residential energy use relative to commuting by a few percentage points at most.

<sup>11</sup>I define a large change in income as a greater than 0.5 (in absolute value) change in log income. This approximates a 50 percent increase/decrease in income and corresponds to about the top quarter in absolute income change in my panel sample.

TABLE 2—PANEL STATISTICS

	Panel sample		Mover sample	
	CBSA	Tract	CBSA	Tract
<i>Panel A. Sample characteristics</i>				
First observed in 2000	0.10	0.10	0.16	0.14
Years between observations	7.9	7.9	10.3	9.8

CBSAs	1,000	1,000	1,000	1,000
Tracts	70,000	61,500	54,500	61,500

Notes: Columns 1 and 2 show panel statistics for the CBSA and tract panel samples. Columns 3 and 4 show panel statistics as well as summary measures of mobility patterns for the CBSA and tract mover samples. All sample statistics are weighted using census sample weights. Sample counts are unweighted and rounded according to Census Bureau disclosure rules.

warmer places. For additional comparisons of movers versus stayers, estimates of the likelihood of moving given shocks to household income, number of children, or changes in homeownership, and the full set of transition probabilities across urban, suburban, and rural places, see the Supplemental Appendix.

### C. Observational Heterogeneity

Carbon emissions from residential energy and commuting vary immensely across individuals in the full sample (see Supplemental Appendix). This variation is strongly correlated with both geographic and household attributes. At the regional level, carbon emissions vary with climate and with the emissions intensity of local fuel sources. At the more local level, many have observed a relationship between emissions and local amenities that characterize urban form, such as local public transit, bike infrastructure, green space, and density (Ou et al. 2013; Philips, Anable, and Chatterton 2022).

Figure 1 presents average household carbon emissions across urban, suburban, and rural neighborhoods. Households residing in suburban and rural areas have substantially higher emissions than those living in urban areas. While those differences could, in theory, result from sorting based on observable household characteristics

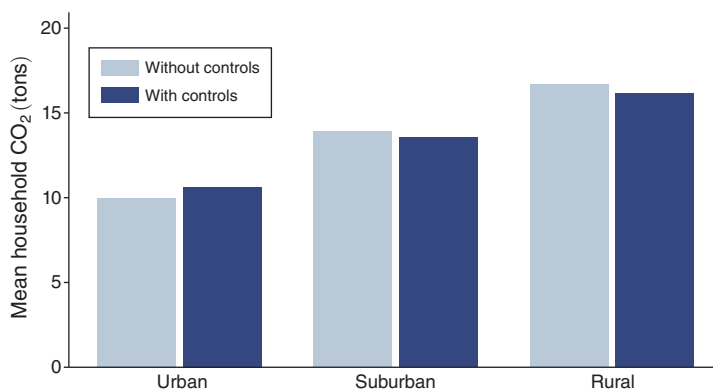

FIGURE 1. HOUSEHOLD CARBON EMISSIONS IN URBAN, SUBURBAN, AND RURAL PLACES

*Notes:* This figure shows estimates of household carbon emissions by urbanity. Estimates are derived from regressions of log carbon emissions (in metric tons) on indicators for urban, suburban, and rural tracts, with year fixed effects. The specification with controls additionally includes age, gender, race, education, household size, number of children, and homeowner status. I define urban tracts according to Dijkstra, Poelman, and Veneri (2019). I define suburban tracts as nonurban tracts within a CBSA. I define rural tracts as those outside CBSAs. Mean household carbon emissions are precisely estimated and statistically different from one another. The unconditional regression has an  $R^2$  of 0.11; the conditional regression has an  $R^2$  of 0.29.

such as college education, race and ethnicity, household income, or number of children, among others (see Supplemental Appendix), controlling for observable household characteristics only marginally reduces the differences between rural, suburban, and urban areas. There is some sorting of higher-emissions households to suburban and rural areas and lower-emissions households to urban areas, but even after accounting for these differences, households in suburban tracts still emit over 20 percent more per year than observationally similar households in urban tracts, while households in rural tracts emit about 50 percent more.

To examine spatial heterogeneity in more detail, I estimate unconditional and conditional tract-level means,  $\mu_j$ , using an ordinary least squares regression of log of household carbon emissions onto place fixed effects, year fixed effects  $\tau_t$ , and in the conditional regression, individual and household observable characteristics  $\mathbf{X}_{it}$ .

$$(1) \quad \ln CO_{2it} = \mu_{j(i,t)} + \mathbf{X}'_{it}\boldsymbol{\beta} + \tau_t + \varepsilon_{it}.$$

I use an empirical Bayes “shrinkage estimator” to adjust the estimates for statistical noise (see Supplemental Appendix for details). In practice, the distributions and relevant moments are almost identical for the adjusted and unadjusted estimates. Figure 2 presents the adjusted conditional and unconditional distributions of  $\hat{\mu}_j$ . I estimate that households living in neighborhoods 1 standard deviation above the mean emit on average approximately 1.9 times more than those living in neighborhoods 1 standard deviation below the mean, or 1.8 times more after accounting for differences in observable characteristics. For the remainder of this paper, I refer to means conditional on observable characteristics as “observational means,” following the terminology used by Abaluck et al. (2021).

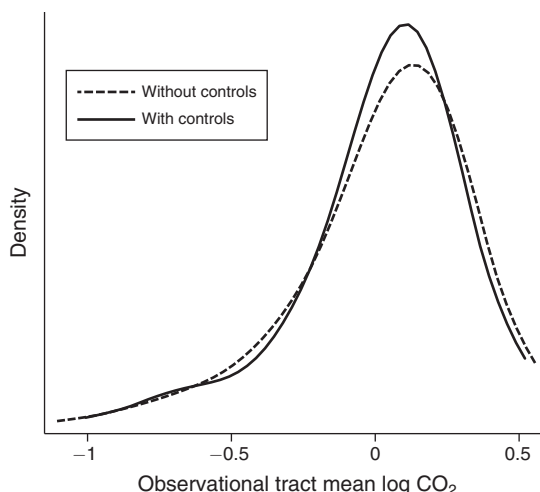

FIGURE 2. HETEROGENEITY IN TRACT-LEVEL CARBON EMISSIONS

*Notes:* This figure shows kernel density estimates, using a Gaussian kernel function, of tract-level observational mean emissions. The distributions are censored at the top and bottom 1 percent of observations in order to abide by Census Bureau Disclosure Avoidance rules. The dotted line labeled “Without controls” corresponds to the distribution of log CO<sub>2</sub> conditional on year fixed effects only and has a standard deviation of 0.33, while the solid line labeled “With controls” conditions on observable household characteristics and has a standard deviation of 0.30. Both distributions are de-meanned to match the model with controls. Observable characteristics include age, gender, race, ethnicity, education, homeowner status, household income, household size, and number of children.

The remaining heterogeneity in observational means reflects some combination of place-based characteristics and unobserved household characteristics. To illustrate this, I rewrite equation (1) as a two-way fixed effects model:

$$(2) \quad \ln CO_{2it} = \alpha_i + \psi_j + \mathbf{X}'_{it}\boldsymbol{\beta} + \tau_t + \varepsilon_{it},$$

where  $\psi_j$  represents the place-based characteristics and  $\alpha_i$  represents the unobserved, fixed, household characteristics. Comparing equation (1) and equation (2) highlights the bias that can arise when inferring place effects from observational means, as  $\mu_j = \psi_j + E[\alpha_i | i \in j]$ . In other words, observational means reflect a combination of place effects and an average over the unobserved characteristics of the residents of a place.

The primary objective of this paper is to disentangle these components and quantify the extent to which heterogeneity in household carbon emissions is driven by unobserved household characteristics and preferences, and how much is driven by causal place effects, that is, the amount by which the same household’s carbon emissions would differ from place to place due to the underlying features of each place, holding household characteristics fixed. This motivates the mover design, which leverages this exact variation.

## II. Model

In the previous section, I demonstrated how a two-way fixed effects model can be used to mitigate biases that arise when making inferences based on observational

means. To provide further insight into the model, I now illustrate how it relates to a standard way of modeling consumer energy demand and discuss the interpretation of place and household effects.

Consider a household,  $i$ , living in place,  $j$ , that consumes quantity  $Q$  of energy in the form of four categories of fuels,  $f$ . In the residential sector, it can consume electricity ( $e$ ), natural gas ( $n$ ), and other heating fuels ( $o$ ). In the transportation sector, it can consume motor gasoline ( $m$ ).<sup>12</sup>

Average demand  $a_j$ , price elasticities of demand  $\rho_j^f$ , and prices  $P_j^f$  are permitted to vary by place. Place-based differences in average energy demand and in price elasticities of demand could stem from a range of fixed and malleable characteristics of places. These characteristics include climate, local public goods and urban form (e.g., density, public transit, pedestrian and bike infrastructure, proximity to highways and availability of parking, and proximity to leisure and commercial amenities), and regulatory characteristics (e.g., zoning restrictions that change the size and density of homes and building codes that change energy efficiency requirements or eliminate natural gas hookups). All of these features could potentially shift energy demand, both on average and in slope.

In addition to place-based characteristics, demand also depends on observable fixed and time-varying household characteristics (such as age, household size, and income)  $\mathbf{X}_{it}$ , individual fixed unobserved determinants of demand (such as a person's intrinsic risk tolerance for biking on shared roads, aversion to public transit versus traffic, or relative enjoyment of spending time in their own backyard versus a public park)  $\alpha_i$ , individual time-varying unobserved determinants of demand (perhaps an increased willingness to bike after reading the latest Intergovernmental Panel on Climate Change report)  $\varepsilon_{it}$ , and national annual variation  $\tau_t$ . Taken together, household demand for residential and transportation energy is given by

$$(3) \quad \ln Q_{it} = a_j + \sum_{f \in \mathcal{F}} \rho_j^f \cdot \ln P_j^f + \mathbf{X}_{it}' \boldsymbol{\beta} + \tau_t + \alpha_i + \varepsilon_{it}.$$

If all households within a place used the same proportion of fuel types, it would be simple to express the above equation, with log carbon emissions as the outcome, in terms of a place-based average emissions factor  $\bar{\phi}_j$ , and to in turn rewrite that expression as the two-way fixed effects model defined in the previous section:

$$(4) \quad \begin{aligned} \ln CO_{2it} &= \ln(\bar{\phi}_j Q_{it}) \\ &= \underbrace{\ln \bar{\phi}_j + a_j + \sum_{f \in \mathcal{F}} \rho_j^f \cdot \ln P_j^f}_{\psi_j} + \mathbf{X}_{it}' \boldsymbol{\beta} + \tau_t + \alpha_i + \varepsilon_{it}. \end{aligned}$$

In this simplified setting, place effects  $\psi_j$  capture the combination of place-based variation in five key factors: average energy demand, fuel price elasticities, fuel

<sup>12</sup>Electric vehicles are a negligible share of driving in my sample time frame. If someone has an electric vehicle, I overestimate their emissions because the electricity they use to charge their vehicle is included in residential energy (if they charge at home), but I also assign them gasoline emissions. As electric vehicles (EVs) become a larger share of the market, observing household vehicle choices, and the place-based role of EV charging networks on these choices, will be critical for future research.

prices, electricity emissions factors, and fuel shares. In reality, fuel shares vary not only across places but also across households. For instance, some states and municipalities are attempting to ban natural gas connections for new construction (O'Brien 2023; Cornfield 2023), but even if natural gas is available as an option, some households may still opt to fully electrify their homes, while others may have a strong preference for cooking on gas stoves.

In the Supplemental Appendix, I examine how the interpretation of the two-way fixed effects model is affected when fuel shares are allowed to vary across individuals. The more complex model includes a term that captures the interaction between fuel emissions factors and a household's fuel shares relative to the place-based average. Because electricity emissions factors vary across places, a household that disproportionately uses electricity will experience a larger drop in emissions when moving from a place with relatively high-emissions electricity to a place with relatively clean electricity, compared to the average household. This lack of separability implies that there is some inherent misspecification in the two-way fixed effects model in this setting.

The model makes two additional simplifications. First, place effects are assumed to be fixed, implying that any time variation, including changes in prices, is absorbed in the place effects, which reflect average differences between places over the sample time frame. Second, while the model allows price elasticities of demand to vary across places, it does not allow for them to systematically vary across households. For example, the model does not allow for different elasticities between high- and low-income households. Allowing for heterogeneity in demand elasticities across household characteristics would introduce additional interaction terms in the error, as elasticities would be interacted with place-specific prices. Together, this interaction along with the interaction between household fuel shares and place-specific electricity emissions factors motivate treating the errors as heteroskedastic.

### III. Empirical Strategy

My empirical strategy uses movers to estimate place effects and their contribution to spatial heterogeneity in carbon emissions. The intuition behind the mover design is the following: Suppose high-emissions places are high-emissions because of causal place effects—for example, because there are no alternatives to commuting other than by car or because zoning regulations impose constraints on minimum home sizes and density. If so, there would be households that live in high-emissions places for work or to be near family or near other amenities they enjoy, which may otherwise make lower-emissions residential and transportation choices but are unable to. If those households move from an on average high-emissions place to an on average low-emissions place where lower-emissions alternatives become available to them, their carbon emissions should decrease. Conversely, if spatial heterogeneity is driven by strong preferences, then households currently living in detached single-family homes and commuting by car would continue to do so even given alternate options, and moving from on average high- to low-emissions places should have little effect on household carbon emissions.

I use the mover design to estimate two versions of a heterogeneity decomposition of household carbon emissions. I begin with an event study, which, under

strong assumptions, characterizes the share of differences *between* places attributable to place effects, inferred from movers' changes in emissions relative to origin-destination mean differences. Under weaker assumptions, the event study serves as additional descriptive evidence and model validation for the second decomposition, as well as unbiased prediction of how carbon emissions will change for the set of observed moves. I then estimate the nonparametric distribution of household and place effects and decompose *overall* heterogeneity into variance components. In the following subsections, I first discuss modeling and identifying assumptions, and then I describe each of these decompositions in more detail.

### A. Main Assumptions

My empirical strategy at its foundation pairs a two-way fixed effect model with a mover design. In order for estimates from this approach to be unbiased, three assumptions need to hold: (i) additive separability of place effects, or constant effects; (ii) nonpersistence of outcomes; and (iii) exogenous mobility, or conditional orthogonality. I discuss each below.

#### ASSUMPTION 1: *Additive Separability of Place Effects, or Constant Effects.*

A core modeling assumption of the two-way fixed effect design is that the outcome—log carbon emissions—is additively separable in household and place effects. The log specification is statistically appealing, as it reflects the approximate log-normality of the household carbon emissions distribution (see Supplemental Appendix). It is also conceptually appealing, as it implies that place effects increase and decrease carbon emissions proportionally by the same amount for everyone, which aligns with many potential mechanisms through which place effects could arise. For example, it is natural to model climate as scaling residential heating or cooling needs up or down by the same factor for all households, regardless of their baseline energy consumption. If density drives place effects, it is reasonable to expect denser places to decrease the size of homes (and therefore residential energy requirements) or the length of commutes (and therefore transportation energy requirements) by the same factor for all households. Similarly, an increase in transportation alternatives to cars might decrease the share of trips taken by car for all households proportionally.

Nevertheless, the two-way fixed effects model imposes a substantial restriction: It does not allow for heterogeneous treatment effects or match effects. Heterogeneous place effects could arise in various scenarios. For instance, a new public transit option might significantly reduce emissions for relatively low-emissions households, while barely affecting high-emissions households' behavior. Paired with changes in density, this could even produce divergent effects if high-emissions individuals find themselves idling in traffic more due to increased congestion. Alternatively, heterogeneous place effects might arise if low-emissions households make the same consumption choices wherever they live, while high-emissions households respond strongly to changes in amenities. Moreover, Section II reveals that there is an interaction between households' fuel shares and local emissions factors; a household that prefers to use electricity for heating will see a larger drop

in emissions when moving to an area with cleaner electricity than a household that prefers natural gas heating, all else equal. This interaction introduces a degree of misspecification into the two-way fixed effect model, rendering it an approximation. The critical question is whether households systematically sort into locations based on this (or any other) interaction. As long as they do not, the mover design will continue to yield unbiased estimates of average place effects.

To rule out selection on heterogeneous effects, I follow Card, Heining, and Kline (2013) and test whether moves from a low-emissions place to a high-emissions place and moves from a high-emissions place to a low-emissions place are associated with equal and opposite changes in household carbon emissions. To see why symmetry rules out selection on heterogeneous effects, consider differences in potential outcomes across an origin  $o$  and destination  $d$ , allowing now for there to be an interaction  $\eta(\alpha_i, \psi_j)$  between person and place types:

$$E[CO_{2it}(d)] - E[CO_{2it}(o)] = (\psi_d - \psi_o) + \eta(\alpha_i, \psi_d) - \eta(\alpha_i, \psi_o).$$

As long as

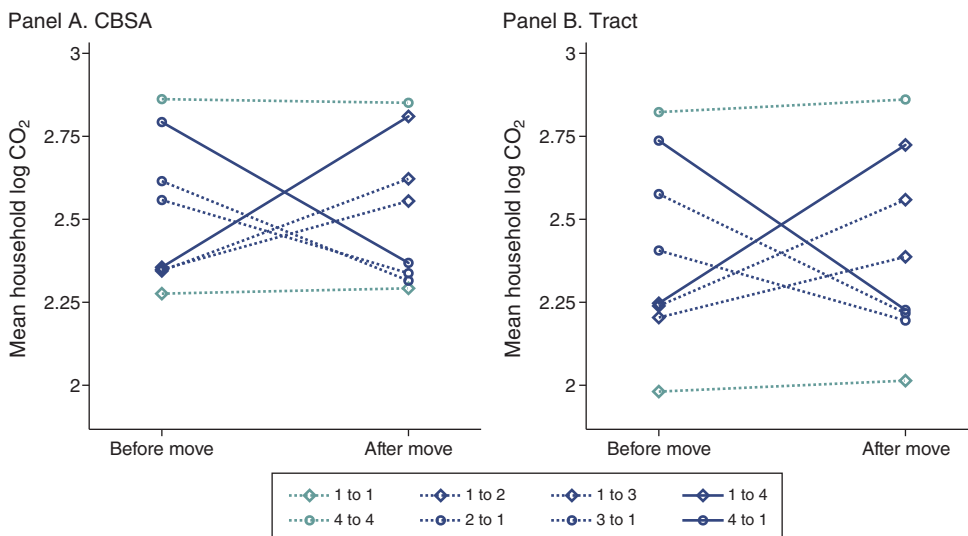

$$(5) \quad \eta(\alpha_h, \psi_d) - \eta(\alpha_h, \psi_o) \neq \eta(\alpha_l, \psi_d) - \eta(\alpha_l, \psi_o),$$

this type of interaction, paired with selection, would lead to asymmetries between changes in household carbon emissions for moves to higher on average places versus moves to lower on average places. Note that condition (5) holds for a broad class of functions, including the simplest interaction,  $\eta = \alpha_i \cdot \psi_j$ , since  $\alpha_i \cdot (\psi_d - \psi_o) \neq \alpha_j \cdot (\psi_d - \psi_o) \forall i \neq j, o \neq d$ .<sup>13</sup> Returning to an earlier example, suppose place effects are due to a public transit option that only low-emissions households use. Suppose also that households that wish to use public transit disproportionately move to places where it is available, whereas households that don't want to use public transit disproportionately move to places where it is not available; the subsequent decline in emissions for households moving from a high-emissions place to a low-emissions place will be larger than the increase in emissions for households moving in the opposite direction.

I group places into four quartiles based on observational averages of carbon emissions, and I estimate household carbon emissions for each origin-destination quartile pair, adjusting for annual trends and controlling for demographic and household characteristics. Figure 3 displays the results. For parsimony, the figure shows only moves from the lowest-quartile emissions places to all four quartiles and vice versa, as well as moves within first-quartile places and moves within fourth-quartile places as bounds in gray.

First and foremost, this figure shows that moves across quartiles lead to equal and opposite changes in household carbon emissions. This symmetry suggests that the log-linear two-way fixed effect model of household carbon emissions is a good approximation for the role of place effects and alleviates concern about selection on heterogeneous treatment effects. Second, this figure provides evidence of selection

<sup>13</sup> More generally, equation (5) implies that  $\frac{\partial \eta}{\partial \alpha}(\psi_d - \psi_o) \neq 0$ , and in turn,  $\frac{\partial^2 \eta}{\partial \alpha \partial \psi} \neq 0$ . In words, the symmetry check rules out any interaction in which the change between places grows or shrinks with household type.

FIGURE 3. CHANGES IN HOUSEHOLD CO<sub>2</sub> WHEN MOVING ACROSS QUARTILES OF MEAN CO<sub>2</sub>

*Notes:* This figure shows average household carbon emissions for movers across places classified into quartiles based on their observational mean carbon emissions in the full sample. Symmetric responses to moves in opposite directions provide support for the log-linear two-way fixed effect model of household carbon emissions because they are consistent with place effects entering log carbon emissions additively. This figure shows only the subset of moves to and from the lowest-emissions places (quartile 1), as well as moves within the highest-emissions places (quartile 4). Estimates are conditional on year fixed effects and the standard set of household characteristics used throughout this analysis. Estimates are weighted by Census Bureau sample weights.

at the tails, particularly for tract-level moves; households that move from the lowest quartile to a different place in the lowest quartile have lower emissions on average than households that move between the lowest quartile and any of the three higher quartiles. Similarly, households that move between places in the fourth quartile have higher emissions than those that move between the fourth and the first, though the difference at the top is less pronounced. Finally, note that households that move between tracts within the same quartile experience a small increase in emissions, consistent with the general trend of households moving to on average higher-emissions places.

#### ASSUMPTION 2: *Nonpersistent Outcomes.*

As highlighted above, I identify relative place effects from pairwise comparisons of household carbon emissions between origin and destination,

$$E[CO_{2it}(d) | \alpha_i, \mathbf{X}_{it}, \tau_t] - E[CO_{2it}(o) | \alpha_i, \mathbf{X}_{it}, \tau_t] = \psi_d - \psi_o.$$

This expression holds for any two households moving between  $o$  and  $d$ , which means that it cannot differ from household to household as a result of differences in their residential histories. In other words, the expected change for two households moving between the same origin and destination should be the same even if one of the households previously lived in Houston, while the other previously lived in New

York. Note, however, that the nonpersistent outcomes assumption does *not* rule out that the place someone was born and raised may have a persistent effect on their preferences and carbon emissions. Because I include household effects in the model and only include individuals over the age of 18 in the sample, any persistent effect of place of birth and upbringing on carbon emissions will be captured by the household fixed effect.

**ASSUMPTION 3: *Exogenous Mobility or Conditional Orthogonality.***

When the first two assumptions hold, the model serves as a reasonable approximation to the real world, and consequently, random variation in exposure to place identifies place effects. Thus the final, identifying, assumption necessary for this empirical approach to be unbiased is that moves are conditionally exogenous; in other words, household destination choices are not related to changes in unobserved determinants of carbon emissions:

$$(6) \quad E[\epsilon_{it} | \alpha_i, \psi_{j(i,t)}, \mathbf{X}_{it}, \tau_t] = 0.$$

It is important to emphasize here that the two-way fixed effects model allows for a broad set of sorting behaviors. First, it allows for unrestricted sorting of households on fixed or time-varying observable characteristics. A key advantage of the census microdata is the ability to observe numerous time-varying household characteristics that could potentially bias the estimates if unobserved. Factors such as entering middle age, having children, experiencing a change in income, or becoming a homeowner are all associated with an increase in energy consumption generally (see Supplemental Appendix), and the latter three also significantly increase the probability of moving (see Supplemental Appendix). However, this endogeneity does not bias the estimates, as I observe age, household size, number of children, household income, and homeowner status and am therefore able to separate the effect of these characteristics on household emissions from their influence on a household's choice of new city or neighborhood.

Second, and crucially, the two-way fixed effect model allows for unrestricted sorting on fixed unobservable characteristics. In other words, if households have heterogeneous, but fixed, preferences for neighborhood amenities—for instance, if someone has a particular distaste for public transit, a strong preference for large homes, or a particular love for walking or biking—and their choice of what neighborhood to live in reflects those preferences, estimates of place effects are unbiased by this selection because household fixed effects capture these unobserved but fixed determinants of carbon emissions. The ability to account for, and allow unrestricted sorting on, these time-invariant unobserved preferences is a critical benefit of the pairing of the two-way fixed effect model and mover estimation strategy.

Note also that the fact that I might never observe a very high-emissions household move to a very low-emissions place is not a problem if you accept Assumption 1, that places do not have heterogeneous effects on different types of households. It is sufficient to have a connected network of pairwise moves between places in

order to identify relative place effects, and household effects are identified relative to other households within the same place. Consequently, even if I observe only lower-emissions households moving from Pittsburgh to New York, and only higher emissions-households moving from Pittsburgh to Houston, a comparison of household emissions within Pittsburgh combined with the observed changes to household emissions at their destinations identifies the relevant household and place effects. I have already provided some evidence that place effects do not appear to be heterogeneous in the symmetry check shown in Figure 3. I will provide additional evidence of this when I examine heterogeneity in the event study results, in Section IVA. If this model assumption is violated and there is selection on heterogeneous treatment effects, then the place effects I estimate should be thought of as local average treatment effects for the population moving to those places.

Thus, the main threat to identification stems from the possibility that moves correspond to *changes* in unobserved preferences—either through an idiosyncratic shock or via preference “drift,” that is, a gradual evolution in preferences that is not captured by aging. Revisiting the example in the previous paragraph, this would reflect a scenario in which the two households in Pittsburgh were initially similar, but then one household becomes increasingly concerned about climate change and makes lifestyle choices to reduce its carbon emissions, subsequently relocating to New York to facilitate these choices, while the other household’s preferences remain unchanged. In this example, the first household’s carbon emissions would have changed to some extent even if it had stayed in Pittsburgh, and that portion of the change would be incorrectly attributed to the New York place effect.

A standard approach for ruling out endogenous moves is to test for parallel trends between movers and stayers prior to the move. Unfortunately, I observe the majority of my sample only twice, which makes this impossible. Instead, I use data from the Panel Study of Income Dynamics (PSID; Lyubich 2024), over the same sample period, and assess whether movers in the PSID exhibit any changes to energy expenditures (defined as monthly spending on electricity, home heating, and gasoline) prior to their move. I do not know where households move from or to, so I look separately at households whose energy expenditures are higher after moving and those whose energy expenditures are lower after moving, controlling for household size, income, householder age, and year fixed effects. I find no evidence of pre-trends for either group (see Supplemental Appendix).

In Section IVA, I will also show evidence on preference “drift.” If moves were endogenous to evolving preferences, the selection component, and consequently, the parameter estimate, would likely increase with the duration since the move. Some evidence of drift emerges in the baseline analysis, but the magnitude of drift appears to be quite small and becomes insignificant when looking at a restricted sample with no observable major life events.

### B. Event Study Decomposition

The first decomposition I estimate is an event study, following the approach used by Finkelstein, Gentzkow, and Williams (2016). The event study begins with the two-way fixed effect model defined in equation (2) but summarizes heterogeneity with a single parameter rather than the full distribution of  $J$  place effects. For

household  $i$  moving from origin  $o$  to destination  $d$ , the expected change in carbon emissions is given by

$$E[\ln CO_{2it}(d) - \ln CO_{2it}(o) | \alpha_i, \mathbf{X}_{it}, \tau_t] = \psi_d - \psi_o.$$

I then express the change in place effects as a share of the differences between observational means:

$$\begin{aligned} \psi_d - \psi_o &= \frac{\psi_d - \psi_o}{\bar{y}_d - \bar{y}_o} \cdot (\bar{y}_d - \bar{y}_o) \\ &\equiv \theta_{o,d} \cdot (\bar{y}_d - \bar{y}_o). \end{aligned}$$

Incorporating this expression into the two-way fixed effect model yields the event study equation, which I use to estimate  $\theta$ , the share of between-place differences attributable to place effects:

$$\begin{aligned} (7) \quad \ln CO_{2it} &= \alpha_i + \psi_j + \tau_t + \mathbf{X}'_{it}\boldsymbol{\beta} + \varepsilon_{it} \\ &= \alpha_i + \psi_o + \mathbf{1}_{\{moved\}} \cdot (\psi_d - \psi_o) + \tau_t + \mathbf{X}'_{it}\boldsymbol{\beta} + \varepsilon_{it} \\ &= \tilde{\alpha}_i + \mathbf{1}_{\{moved\}} \cdot \theta \cdot (\bar{y}_d - \bar{y}_o) + \tau_t + \mathbf{X}'_{it}\boldsymbol{\beta} + \varepsilon_{it}. \end{aligned}$$

By characterizing the place share of heterogeneity with a single parameter,  $\theta$ , the event study approach vastly reduces the dimensionality of the estimation problem. This efficiency comes at the cost of an additional assumption: In order for  $\hat{\theta}$  to reflect an unbiased, causal parameter, it cannot be correlated with other parameters in the model. In other words, unlike the two-way fixed effect model, this approach does not permit systematic sorting of certain types of households, either based on observable characteristics or unobservable types, to certain types of places. This is because it infers place types from observational means; if there were sorting of, for example, high-type households to high-type places,  $\bar{y}_d - \bar{y}_o$  would grow faster than  $\psi_d - \psi_o$  as places grow more different, leading to biased estimates.

The stronger restriction on sorting is more plausible at the CBSA level, in which people are more likely to move for job opportunities or to be close to family, than at the neighborhood level, where choices are more likely to be driven by local amenities. In Section IVA I will provide evidence that estimates of the share parameter are not heterogeneous along several dimensions, suggesting little bias from this stronger assumption. However, even under weaker baseline assumptions, under which event study results can't be interpreted as causal, the results remain informative for two reasons. First, they serve as useful descriptive evidence and additional model intuition and validation for the Kline, Saggio, and Sølvssten (2020)—henceforth, KSS—analysis to come. Second, they yield unbiased predictions about how household carbon emissions will change for any set of observed moves. This is particularly useful, as researchers have highlighted that restrictive zoning and high cost of living in productive areas drives people to higher-emissions

locations (Glaeser and Kahn 2010). The labor and urban literatures have identified that such moves lead to decreased welfare due to loss of agglomeration externalities. The event study specification makes it possible to additionally estimate the carbon emissions externality of these regulatory restrictions.

### C. Variance Decomposition

The second decomposition is based on the full set of nonparametric fixed effect estimates from the model. Specifically, heterogeneity in household carbon emissions can be decomposed as below, lumping  $\tau_t$  with  $\mathbf{X}_{it}$  for brevity:

$$(8) \text{ var}[y_{ij}] = \text{ var}[\psi_j] + 2 \cdot \text{ cov}[\alpha_i, \psi_j] + \text{ var}[\alpha_i] \\ + \text{ var}[\mathbf{X}'_{it}\beta] + 2 \cdot \text{ cov}[\alpha_i, \mathbf{X}'_{it}\beta] + 2 \cdot \text{ cov}[\psi_j, \mathbf{X}'_{it}\beta] + \text{ var}[\varepsilon_{it}].$$

This analysis focuses on the first three terms: the variance component of place effects, the variance component of unobserved person effects, and their covariance, which captures the spatial heterogeneity that results from systematic sorting on unobserved preferences. Each variance component describes the share of *overall* heterogeneity attributable to the relevant component.

In contrast to the event study decomposition, the two-way fixed effects decomposition allows unrestricted sorting of households across places; it imposes no limitations on the magnitude or sign of the covariance terms. This flexibility comes at an econometric cost. A well-documented challenge to estimating variance components in two-way fixed effect models is limited mobility bias (Andrews et al. 2008). Limited mobility bias arises because place effects are estimated based on the outcomes of people who move between different locations; however, for any given place, there might only be a small number of people moving in or out. This can lead to imprecise estimates, which creates an upward bias in the naïve plug-in variance estimate relative to the true variance of place effects, even if estimates of place effects themselves are unbiased. To address this, I estimate variance components using the heteroskedasticity-unbiased leave-out estimator proposed by KSS. The KSS estimator uses a leave-out estimate of standard errors to correct estimates of the variance components for sampling variability.

I implement the leave-out estimator at the household level, leaving out all observations corresponding to a household match. In the mover sample, the KSS estimator is robust to unrestricted heteroskedasticity and serial correlation within each match. Because it is not possible to leave out matches for stayers without dropping all their observations, if there is serial correlation in the error term, KSS estimates of the person variance component in the panel sample are an upper bound on the true value. See the Supplemental Appendix for additional computational details, and KSS for a complete discussion of the leave-out estimator.

## IV. Results

This section presents the core results of my paper: estimates of the share of heterogeneity in household carbon emissions attributable to place effects. I begin by

TABLE 3—SHARE OF SPATIAL VARIATION IN MEAN CO<sub>2</sub> ATTRIBUTABLE TO PLACE EFFECTS

	CBSA			Tract		
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Panel A. Panel sample</i>						
Place share of mean difs.	0.91 (0.008)	0.86 (0.007)	0.86 (0.016)	0.78 (0.003)	0.60 (0.003)	0.55 (0.007)
Observations	1,764,000	1,764,000	633,000	1,710,000	1,710,000	613,000

Household controls		X	X		X	X
No big life events			X			X

*Notes:* This table reports event study estimates of the place share of spatial heterogeneity in household carbon emissions. The place share estimate ( $\hat{\theta}$ ) represents the proportion of differences in average carbon emissions ( $\bar{y}$ ) between a mover's origin and destination attributable to place effects. Panel A reports estimates from the panel sample, while panel B restricts the sample to movers only, allowing for systematic differences between movers and stayers. Columns 1 and 4 show estimates from CBSA and tract moves, respectively, with only year fixed effects. Columns 2 and 5 add controls for the standard set of household characteristics. Columns 3 and 6 restrict the sample to households without changes in number of children, income changes exceeding 50 percent, or changes in homeownership. All estimates use Census Bureau sample weights.

showing results from the event study specification, which—even if the stronger assumptions on selection are violated—serve as additional descriptive evidence and can be used to predict how household carbon emissions will change for movers under existing patterns of mobility. I then present results from the variance decomposition of the unrestricted two-way fixed effect model. I conclude the section with a discussion on interpreting the two versions of the analysis.

### A. Event Study Decomposition

This section presents estimates from the event study derived in Section IIIB:

$$\ln CO_{2it} = \tilde{\alpha}_i + \mathbf{1}_{\{moved\}} \cdot \theta \cdot (\bar{y}_{d-i} - \bar{y}_{o-i}) + \tau_t + \mathbf{X}'_{it} \boldsymbol{\beta} + \varepsilon_{it},$$

where  $\bar{y}_{j-i}$  are sample means estimated from the full sample, leaving out the household observation.<sup>14</sup>

Table 3 presents event study estimates of  $\hat{\theta}$ , which captures the share of differences between observational place means attributable to differences between place effects. Columns 1–3 show results from regressions examining CBSAs, while columns 4–6 show results from regressions examining tracts. Panel A shows results

<sup>14</sup>To the extent that there is sampling variability in the distribution of observational means, my estimate of the relationship between origin-destination mean changes and individual changes in log CO<sub>2</sub> may be biased. In practice, using a linear empirical Bayes estimator to adjust means for sampling variability does not materially change the results.

estimated from the panel sample, which consists of both movers and stayers; panel B shows results using just the mover sample. Both samples use mover variation to identify place effects, but estimates may differ if the relationship between household characteristics and emissions varies systematically between movers and stayers. For instance, if having children induces divergent preference shocks—prompting movers to seek larger, potentially higher-emission homes, while reinforcing stayers’ preference to be within walking distance of friends and local amenities—including stayers in the analysis could underestimate the direct impact of children on movers’ emissions, thereby overstating the place effect. Across specifications, the mover sample yields place share estimates that are at most 4 percentage points lower than the panel sample estimates. This implies that movers and stayers have only marginally different responses to changes in observables, and including stayers introduces a small upward bias in the place effect estimates.

Columns 1 and 4 present estimates from a model with just year fixed effects. These estimates show that when a household moves, its emissions change by 89–91 percent of origin-destination CBSA mean differences and 76–78 percent of origin-destination tract mean differences. However, these estimates are confounded by the correlation between household characteristics and location choices. Columns 2 and 5 address this by controlling for observable household characteristics (age, household income, household size, number of children, and homeowner status) that likely influence both emissions and neighborhood choice. This adjustment reduces CBSA share estimates by up to 5 percentage points (to 85–86 percent) and tract share estimates by nearly 20 percentage points (to 57–60 percent). The larger impact on tract-level estimates suggests that, as you would expect, household sorting plays a more significant role in neighborhood-level emissions variation, while CBSA-level moves may be driven more by factors like job opportunities or family considerations. In the Supplemental Appendix, I reestimate columns 2 and 5 controlling for average heating degree days, cooling degree days, and electricity emissions factors. Doing so decreases the CBSA share to 68–70 percent and the tract share to 51–54 percent. While these estimates lend insight into the mechanisms underlying place effects, I focus my main event study analysis on total place effects, which are more relevant for predicting emissions changes from observed migration patterns.

Even after accounting for the rich set of observable characteristics available in the data, household destination choices may still be influenced by unobserved heterogeneous preference shocks. While I cannot rule this out entirely, I explore the potential bias from such selection by restricting the sample to households with minimal observable shocks, motivated by the premise that these households are less likely to have experienced large concurrent unobservable changes. Columns 3 and 6 present results from this “no big life events” subsample, which excludes households that experienced a change in the number of children, a greater than 0.5 log point change in income, or a change in homeownership status between observations. This subsample, comprising approximately 20 percent of the original observations, yields place share estimates at most 5 percentage points lower than the baseline estimates. The fact that households least likely to have experienced unobservable shocks yield qualitatively similar place share estimates to the baseline sample is reassuring and suggests limited bias from shocks to unobserved preference heterogeneity.

FIGURE 4. TRACT SHARE OF SPATIAL VARIATION, BY DURATION BETWEEN OBSERVATIONS

*Notes:* This figure shows event study estimates of the share of spatial variation in mean carbon emissions that can be explained by place effects, by duration between mover observations. In other words, each coefficient is the estimate for place effects generated from the subsample of households that I observe  $x$  years apart. Coefficients plotted in light gray are estimated from the model using the full panel of stayers and movers. Coefficients plotted in the dark blue are estimated from the model using the subsample of stayers and movers with no changes in the number of children, less than 50 percent change in household income, and no change in homeownership status between observations. All estimates are weighted using census sample weights.

In addition to unobserved shocks, another potential source of bias arises from “preference drift”—gradual changes in households’ preferences over time that are not fully captured by changes in age or other observable characteristics (Card, Heining, and Kline 2013). If such drift exists and influences relocation decisions, place effect estimates would conflate true causal effects with selection, particularly for moves observed after long time intervals. This would manifest as place effect estimates that trend upward with the duration between observations. To explore this possibility, Figure 4 presents tract-level place share estimates by duration between observations, controlling for demographic and household characteristics. The light gray points depict estimates for the baseline mover sample, while the dark blue bars correspond to the restricted subsample of movers with no big life changes between observations.

For the full mover sample, a slight upward trend emerges, with place share estimates for durations in the 15- to 19-year range exceeding the pooled estimate. This pattern dissipates when considering the restricted subsample of movers without observable big life changes; the pooled estimate for this group is not contained within the 95 percent confidence interval for 4 out of the 19 duration-specific estimates, but with no clear trend across durations. The Supplemental Appendix presents analogous CBSA estimates, which exhibit a similar pattern, except the upward trend observed in the longer-duration coefficients becomes insignificant in the baseline mover sample as well.

While these results suggest some preference drift, potentially leading to upward-biased place share estimates, the magnitude appears small relative to observed changes in emissions between places, and this bias appears to be negligible in the sample restricted to households without big life events. One additional result

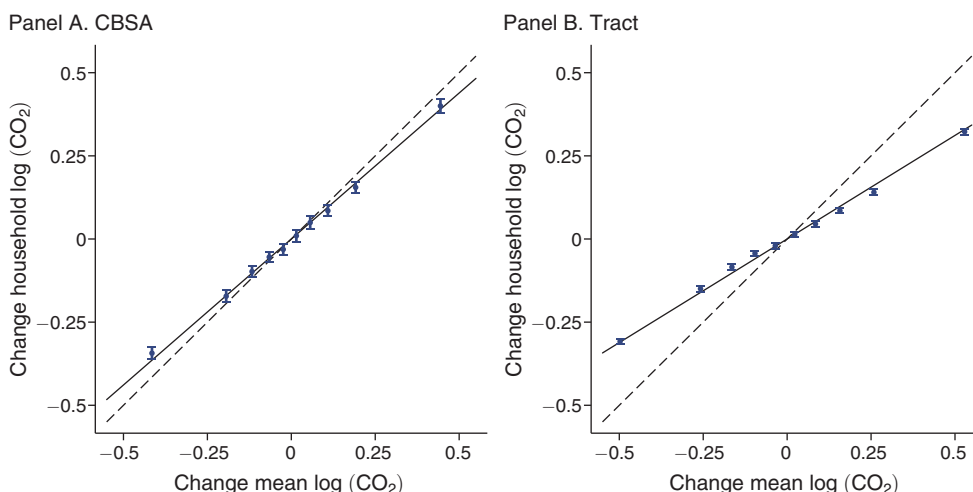

FIGURE 5. PLACE SHARE OF SPATIAL VARIATION, BY MOVE TYPE

*Notes:* This figure shows mover changes in household carbon emissions, by size of origin-destination differences in mean carbon emissions. All estimates are from a model that conditions on changes in observable household characteristics and year fixed effects. I split movers into 10 deciles, according to the size of the (conditional) gap in mean carbon emissions across their origin and destination, and estimate standard errors using bootstrap. Point estimates are shown with 95 percent confidence intervals. The solid lines show the regression estimates from the pooled model, and the dotted line denotes 45 degrees, that is, the scenario in which moving to on average higher- or lower-emissions places leads to a one-for-one increase in own carbon emissions. All estimates are weighted using Census Bureau sample weights.

that emerges from this analysis is that household carbon emissions appear to change instantaneously, suggesting place effects stem from attributes that directly impact emissions rather than gradual influences like peer effects or habit formation.<sup>15</sup>

As a final specification check, I explore heterogeneity across moves of different magnitudes in terms of place mean changes. A potential concern with the results presented thus far is that households choosing to relocate from low-emissions places to high-emissions places (or vice versa) may systematically differ from those moving between areas with similar emissions levels. If a household's choice of destination reveals newly observable information about unobserved preference shocks, the estimates would be biased, mistakenly attributing these shocks to place effects. To explore this possibility, Figure 5 depicts changes in mover households' carbon emissions across deciles of origin-destination mean differences, controlling for demographic and household characteristics. The *x*-axis represents conditional changes in mean emissions between origin and destination, while the *y*-axis shows to conditional changes in household emissions. The 45-degree line (in gray) represents a scenario in which place effects fully explain variation in carbon emissions across locations. The solid line's slope corresponds to the pooled estimate of the relationship between tract-level mean changes and household-level changes. Standard errors are estimated using bootstrap.

<sup>15</sup> While I don't observe how long ago a household moved, the expected time since moving increases with the duration between observations.

I find that, for both moves across CBSAs and moves across neighborhoods, changes in household carbon emissions as a share of changes in origin-destination means are symmetric and linear across move types. In other words, the share of spatial heterogeneity attributable to place-based differences is consistent for moves from low- to high-emissions places (rightmost points), moves from high- to low-emissions places (leftmost points), and moves between places with similar average emissions (central points). The symmetry and stability of share estimates have several implications. First, this result extends the symmetry check presented in Figure 3, further validating the log-linear model specification and suggesting that the two-way fixed effect model reasonably approximates household carbon emissions. Recall that this implies place effect estimates are unbiased even if I never observe some household types moving to some place types. Second, this result indicates that the event study estimates presented in Table 3 are not driven by a subset of movers or mover destinations, alleviating concerns that estimates primarily reflect changes in the emissions of households who moved to a vastly different destination in response to a large unobserved preference shock. Lastly, this result provides another dimension along which heterogeneity in the estimated share parameter appears to be limited.

In summary, the event study estimates indicate that movers' carbon emissions change by over half of origin-destination differences in neighborhood means (and about 85 percent of origin-destination differences in CBSA means) when they move. Under strong assumptions on sorting, this can be interpreted as a causal share parameter, which would determine the change in carbon emissions resulting from any household moving between any pair of places. I estimate that heterogeneity in the share parameter is limited along several dimensions explored throughout this section—estimates are within a 5 percentage point range of each other across subsamples with vastly different changes to observed characteristics, across different observation time horizons, and across varying move types (between similar versus dissimilar places)—suggesting that perhaps bias from violations of this assumption may also be minimal.

Under weaker assumptions, the event study estimates serve as a useful specification check for the two-way fixed effect model, and perhaps more interestingly, they provide unbiased prediction of how household carbon emissions will change for any *observed* move. Recent research and media coverage have highlighted a pattern of increasing migration from more expensive but on average lower-emissions places to less expensive but on average higher-emissions places (Kolko 2021; Eisen 2019). For instance, in 2019, there was a net migration of about 45,00 people from California to Texas. While not all these moves were from San Francisco to Houston, using these two cities as an illustrative example, carbon emissions in Houston are about 21 percent higher than they are in San Francisco (Jones and Kammen 2014). Combined with the event study findings, this implies that regulatory constraints that restrict housing, increase the cost of living, and drive this pattern of migration increase household carbon emissions by 12 percent or more, imposing a sizable carbon externality.<sup>16</sup>

<sup>16</sup>The 12 percent figure would correspond to treating San Francisco and Houston as neighborhoods. If we were to treat them more like CBSAs, the predicted increase in emissions would be closer to 19 percent.

TABLE 4—UNOBSERVED HETEROGENEITY IN CO<sub>2</sub>: VARIANCE DECOMPOSITION

*Notes:* This table reports results from the heteroskedasticity-robust KSS estimation of variance components. For each sample and specification, the table reports the overall outcome variance, the share of variance attributable to place effects ( $\psi_j$ ), the share of variance attributable to household effects ( $\alpha_i$ ), the correlation between place effects and household effects (which captures how much households sort on unobserved characteristics), and the bias-corrected standard deviation of place effects. All specifications include year fixed effects and the standard set of household controls used throughout the paper. Columns 1 and 5 report the baseline variance decompositions at the CBSA and tract levels. Columns 2 and 6 add controls for local mean heating degree days, cooling degree days, and log electricity emissions factors. Columns 3 and 7 additionally control for a price index, constructed from lagged fuel shares interacted with national retail prices. Finally, column 4 computes time-varying CBSA place effects using five-year periods (2000–2004, 2005–2009, 2010–2014, and 2015–2019), using stayer observations across periods to identify time variation in place effects, while movers, as before, identify cross-sectional variation.

### B. Variance Decomposition

In this section, I weaken the restriction on sorting imposed by the event study and present estimates from the variance decomposition shown in equation (8):

$$\begin{aligned} \text{var}[y_{ij}] &= \text{var}[\psi_j] + 2 \cdot \text{cov}[\alpha_i, \psi_j] + \text{var}[\alpha_i] \\ &\quad + \text{var}[\mathbf{X}'_{it}\beta] + 2 \cdot \text{cov}[\alpha_i, \mathbf{X}'_{it}\beta] + 2 \cdot \text{cov}[\psi_j, \mathbf{X}'_{it}\beta] + \text{var}[\varepsilon_{it}]. \end{aligned}$$

For each sample and specification, Table 4 presents the overall variance of the outcome, log(CO<sub>2</sub>); the share of variance attributable to each of the unobserved heterogeneity components (place effects,  $\psi_j$ , and household effects,  $\psi_i$ ); the correlation between the unobserved heterogeneity components; and the bias-corrected standard deviation of place effects. The top panel presents estimates from the entire panel of movers and stayers, while the bottom panel presents estimates from the mover-only sample.

Columns 1 and 5 present the baseline analysis, which includes year fixed effects and the standard vector of household controls. I estimate that CBSA effects account for 14–16 percent of overall heterogeneity (column 1), and tract effects account for 22–23 percent of overall heterogeneity (column 5). Columns 2 and 6 introduce

controls for mean heating degree days, cooling degree days, and log electricity emissions factors, excluding their impact on household emissions from estimated place effects. This specification not only provides insight into the mechanisms driving place effects, as in the event study analysis, but also allows for more precise counterfactual analysis within the KSS framework. When considering interventions that impact household carbon emissions through changes to local amenities and the built environment, isolating the place effect component not driven by climate or electricity-generating sources may be more relevant, though the appropriate specification remains context dependent. For instance, a city-wide initiative to install solar panels on parking lots, potentially coupled with EV charging stations, could decrease the average emissions intensity of electricity while promoting EV adoption. Moreover, while regional climate is, to first order, exogenous to local actions, there are many interventions cities and neighborhoods could enact to decrease heat island effects and in turn reduce local heating degree days (Druckenmiller 2023).

I find that controlling for climate and electric grid intensity together decreases the CBSA share of spatial heterogeneity by roughly 10 percentage points, or by more than half, to 4–7 percent of overall heterogeneity. At the neighborhood level, controlling for climate and electric grid intensity decreases the place share of heterogeneity by roughly 6–7 percentage points (column 6), by less than half, leaving the remaining neighborhood attributes explaining approximately 15 percent. In columns 3 and 7, I additionally partial out variation driven by prices, using a price index constructed from interacting local lagged fuel shares with national retail prices. This does not further change the results at either the CBSA or tract level.

In the Supplemental Appendix, I control separately for electricity emissions factors and climate, and I find that the majority of the decline in place share observed in columns 2 and 6 comes from controlling for electricity emissions factors. It is well understood that climate has a robust effect on energy demand (e.g., Goldstein, Gounaridis, and Newell 2020; Levinson 2016), so why the disparity? Many places that are otherwise low-emissions are in regions that have made efforts to decarbonize their electricity (Murray and Maniloff 2015; Petek 2020), so there is a positive correlation between electricity emissions factors and high other emissions attributes. In contrast to this, I estimate a negative correlation between having above-average heating degree days and low other carbon emissions attributes; many colder cities are in the Northeast, a region that disproportionately contains older, denser cities and neighborhoods (Tomer et al. 2021). These correlation terms enter the place effect variance component, amplifying it when electricity emissions factors are included in the place effect and diminishing it when heating and cooling degree days are included.

Across all three specifications discussed so far, estimates of the place share of heterogeneity are quite comparable between the panel and mover sample. This is not true of the estimates of the household components; a comparison between the panel sample and the mover sample reveals that the contribution of unobserved household characteristics to overall heterogeneity is highly sensitive to which sample the model is estimated on. In the panel sample, unobserved household heterogeneity accounts for 50 percent of overall heterogeneity when defining place at the CBSA level, and 36 percent when measuring place at the neighborhood level. Using the mover-only sample substantially decreases the unobserved household contribution across specifications, to 14–17 percent in the CBSA specification and 10 percent

in the tract specification. The correlation estimates between unobserved place and household characteristics are also sensitive to sample choice, increasing across all specifications by up to 8 percentage points when switching from the panel to the mover sample. This suggests some assortative matching of household types to place types (especially neighborhoods), but in the specification where the correlation coefficient is largest, it remains relatively low, at under 20 percent. The share of overall heterogeneity attributable to matching implied by the covariance term (which is not shown in Table 4 but can be computed from the correlation coefficient and variance components) is less than 5 percent across all specifications.

The panel and mover samples may yield different estimates due to inherent differences between stayers and movers, or KSS's inability to correct for serial correlation in stayers' error terms. To distinguish between these causes, I compare the KSS decomposition estimates with an uncorrected Abowd, Kramarz, and Margolis (1999)—henceforth, AKM—decomposition, presented in the Supplemental Appendix. If differences between stayers and movers drive the discrepancy, both KSS and AKM estimates should reflect this pattern. Conversely, if serial correlation in stayers' error terms is the main factor, AKM should show similar relative contributions of unobserved household heterogeneity across samples (both inflated due to limited mobility bias), with significant differences emerging only after the KSS correction. The AKM estimates reveal relatively stable place and household shares across panel and mover samples, with only minor reductions in the household component's relative size in some specifications. This contrasts with the more dramatic shifts observed in the KSS analysis, suggesting that KSS estimates of household variance components are likely more reliable in the mover sample. Panel sample estimates likely represent an upper bound, with upward bias primarily driven by serial correlation in stayer error terms. The Supplemental Appendix discusses potential sources of this serial correlation, many arising from the survey nature of the data, and their implications for result interpretation. Additionally, the Supplemental Appendix evaluates the sensitivity of results to alternative outcome definitions in the KSS decomposition.

Up until now, I have been estimating place effects pooling over the entire sample time frame; however, place effects may evolve over time in ways that differ from national average trends in carbon emissions. Local or state governments particularly concerned about climate change may enact regulatory changes or make place-based investments aimed at reducing emissions for their residents. Changes to place effects could also arise from local or regional planning initiatives motivated by factors completely unrelated to decision-makers' climate objectives. For instance, the Phoenix metropolitan area—one of the fastest growing metropolitan areas in the United States—grew by nearly 1.6 million residents between 2000 and 2020. This period of growth has been accompanied by a mix of suburban expansion, urban development, the opening of a new light rail system, and several highway expansions (Maricopa Association of Governments 2020). To allow for such place-specific changes, I follow Lachowska et al. (2023) and estimate time-varying fixed effects  $\psi_{jt}$  at the CBSA level, using stayers to identify variation across time within place.<sup>17</sup>

<sup>17</sup> Because tracts by definition consist of many fewer observations than CBSAs, including a time-varying component introduces either substantial noise, or a substantial geographic restriction to only the most populated tracts, so I do not estimate time-varying tract effects. Studying neighborhood-level changes is an important direction for future study.

To maintain connectivity in my set of places, and because for the most part places evolve slowly, I define the time-varying place effects using five-year intervals. Thus, there's a different time-varying place effect for each period: 2000–2004, 2005–2009, 2010–2014, and 2015–2019. Results are shown in column 4 of Table 4; allowing CBSA effects to evolve increases their variance share by only 1 percentage point relative to the baseline specification. This implies that changes in places over my sample period are either mostly captured by national secular trends or are unrelated to household carbon emissions. In the Supplemental Appendix, I provide some descriptive results on the nature of changing time-varying place effects in my sample. I also discuss some of the ways in which place effects may have evolved following the COVID-19 pandemic and the ensuing transition to remote work, which was accompanied by a steep decline in commuting and a shift toward larger homes to accommodate home offices (Van Nieuwerburgh 2023; D'Lima, Lopez, and Pradhan 2022).

As a final specification test, in the Supplemental Appendix, I show binned scatterplots similar to those presented in Section IVA, but now with deciles of changes in estimated place effects rather than observational means, on the x-axis. I plot these against two sets of changes in household mean outcomes: changes for the full mover sample and changes in the sample restricted to only households with no big life events. In a correctly specified model, changes in place effects should lead to one-for-one changes in household carbon emissions, though attenuation bias from noisily estimated place effects is expected to decrease the slope by some. This is roughly what I observe. Moreover, I find no discernible difference between the primary sample and the subsample of households experiencing no big life events, which provides additional reassurance that selection on heterogeneous preference shocks isn't a first-order threat to identification in my analysis.

### C. Interpreting Decomposition Results

How do the event study and KSS results inform one another? First, recall that event study estimates are unbiased only if heterogeneity in the share parameter is uncorrelated with observed and unobserved household characteristics. I have shown evidence that the event study estimates are fairly stable across several observable dimensions of heterogeneity in the data. I also showed in the KSS decomposition that the covariance between unobserved components of heterogeneity is relatively small; the largest correlation coefficient across the four baseline estimates corresponding to the specifications examined in the event study is 0.08. Together, this evidence suggests that bias from this assumption on selection should be minimal.

Second, even when unbiased, the event study yields estimates of shares of mean differences *between* places attributable to place effects, while the KSS estimates yield a variance decomposition of *overall* variation, and this can lead to meaningful discrepancies in magnitudes. To help illustrate this, consider a simplified version of the two-way fixed effects model, where  $y_{it} = \alpha_i + \psi_j + \varepsilon_{it}$ . Song et al. (2019) show that unobserved heterogeneity can be decomposed further into a between-place component  $\text{var}_j[\bar{y}_j]$ , which captures the variation in mean household carbon emissions across places, and a within-place component

$\text{var}_i[y_{it} - \bar{y}_j | i \in j]$ , which captures the heterogeneity in carbon emissions of households living in the same place:

$$(9) \quad \text{var}[y_{it}] = \text{var}[\bar{y}_j] + \text{var}_i[y_{it} - \bar{y}_j | i \in j]$$

$$= \underbrace{\text{var}[\psi_j] + 2 \cdot \text{cov}[\bar{\alpha}_j, \psi_j] + \text{var}[\bar{\alpha}_j]}_{\text{Between}} + \underbrace{\text{var}[\alpha_i - \bar{\alpha}_j] + \text{var}[\varepsilon_{ij}]}_{\text{Within}}.$$

Equation (9) highlights that heterogeneity between places reflects variation in place effects, sorting of certain types of households to certain types of places (the covariance term), and “segregation” of households—the extent to which households of different types segregate across places, whether or not this pattern reflects systematic sorting on place types.<sup>18</sup> In addition to the between-place heterogeneity, overall heterogeneity reflects heterogeneity in household carbon emissions within places, as well as heterogeneity that cannot be explained by the two-way fixed effects model.

For intuition, imagine two places, one  $\psi_{low}$  and one with  $\psi_{high}$ , with identical populations. If there is high variation in carbon emissions within populations and a small difference between  $\psi_{low}$  and  $\psi_{high}$ , the event study would yield a share coefficient of one (since populations are identical across places, all between differences are driven by place effects), but the KSS decomposition would yield a place variance component of close to zero (because of a large within component to the variance). In practice, this is very close to what happens at the CBSA level; the vast majority (85 percent) of differences between CBSAs can be attributable to variation in place effects and not household attributes, but there is much more variation in household carbon emissions within CBSAs than there is across, leading to a variance component of approximately 15 percent in the KSS estimation (more than half of which is attributable to climate and electric grid intensity). At the neighborhood level, household sorting contributes more to variation between places, dropping event study estimates of the place share to roughly 55–60 percent. Accounting for variation within neighborhoods in the denominator decreases the neighborhood share to 22–23 percent of overall heterogeneity, or about 15 percent when excluding climate and electric grid intensity from place effects.

## V. The Characteristics of Low- and High-Emissions Places

With estimates of place effects in hand, I proceed to characterizing high- and low-emissions places. As highlighted in the conceptual model, place effects reflect a mix of differences in demand for energy services, energy prices, energy demand elasticities, fuel mixes, and emissions factors. The urban planning literature has identified many local amenities that could contribute to differences in average household energy demand and energy demand elasticities. In the residential energy sector, larger homes tend to use more energy, as do single-family homes; there is a strong relationship between carbon emissions and density, though it is potentially

<sup>18</sup>  $\bar{\alpha}_j \equiv E[\alpha_i | i \in j]$ .

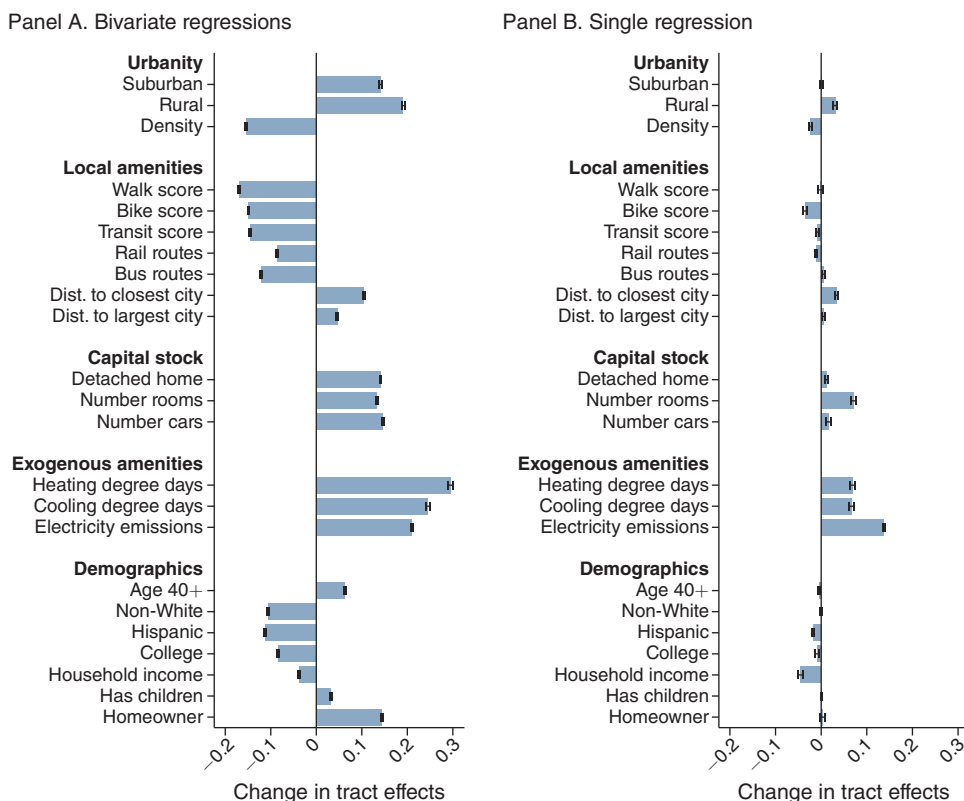

FIGURE 6. CORRELATES OF TRACT EFFECTS

*Notes:* This figure presents estimates from OLS regressions of estimated tract effects on a set of observable place-based and household characteristics. Panel A shows results from separate bivariate regressions, while panel B shows results from a single regression on all covariates. All amenity variables are tract-level means, normalized to have mean 0 and standard deviation 1, except the rural and suburban indicators, which are retained as indicators. Regressions are weighted using ACS sample weights. Thus, estimated coefficients reflect the average change in place effect—and in turn the percent change in carbon emissions, given the log specification of the model—associated with a 1 standard deviation change in observable characteristics.

nonmonotonic due to the effect of density on microclimates; and parks, plants, and green surface coverage are all negatively correlated with energy use (see, e.g., Ko 2013 for a review). In the transportation sector, car use is lower in places with better public transportation, less parking, and more direct road connectivity (e.g., Transportation Research Board 2009; Barrington-Leigh and Millard-Ball 2017), and mechanically, people drive fewer miles when they live closer to where they work, shop, and spend their leisure time. Many of these amenities are intertwined and simultaneously relate to residential and transportation emissions, underscoring the value of studying these sectors together. For instance, higher density not only implies smaller homes but also enables more efficient public transportation networks by reducing distances between transit stops and destinations.

In Figure 6, I show the results from regressions of estimated tract effects onto a set of observational tract-level characteristics. In panel A, I show coefficients from bivariate regressions of tract effects onto each of the shown tract-level characteristics

independently (except for suburban and rural, which are estimated in a single regression), while in panel B, I show coefficients from a single regression onto all of the characteristics.<sup>19</sup> Observable characteristics are all measured at the tract level and are normalized across tracts to have mean 0 and a standard deviation of 1 (except for suburban and rural, which are retained as indicators). Thus, coefficients should be interpreted as showing approximately the average percent change in carbon emissions associated with a 1 standard deviation change in neighborhood-level observable characteristics.

Observable characteristics fall into five categories. Both “urbanity” and “local amenities” cover aspects of urban form that households effectively taken as given but that vary neighborhood to neighborhood. These include whether a tract is urban, suburban, or rural, its density, measures of local public transportation amenities (walk scores, bike scores, transit scores, number of nearby rail routes and bus routes), and measures of sprawl (captured by geodesic distance between tract centroids and the centroid of the closest city and the largest city within the CBSA). “Capital stock” characteristics reflect household choices among the set of options available in a place, which are determined at least in part by local zoning regulations or other policies. These include the share of single-family detached homes, average house sizes, and the number of cars in a household. “Exogenous amenities” are predominantly shaped by factors beyond local control, and households also take these as given. These include annual heating degree days, annual cooling degree days, and electric grid intensity.<sup>20</sup> Finally, the “demographics” category captures tract-level variation in household observable characteristics.

The results of the bivariate regressions (panel A) are consistent with observational data and conclusions in the urban planning literature. Higher-emissions neighborhoods tend to be less urban and dense, with poorer walkability, bikability, and public transit options, and are typically situated farther from city centers within their CBSA. Higher-emissions neighborhoods feature a higher proportion of detached and larger homes, with households owning more cars on average. They experience less mild climates and have higher electricity emissions factors. Finally, looking at the projection of tract effects onto demographics, I find that non-White, Hispanic, college-educated, and higher-income households are more likely to live in low-emissions tracts, while older households, households with children, and homeowners are more likely to live in high-emissions tracts.

When including all of these characteristics in a single regression (panel B), directionally, the relationships remain the same, but many of the coefficient magnitudes decrease substantially. Electricity emissions factors, heating degree days, and cooling degree days emerge as three of the four strongest correlates of place effects. The second-largest correlational coefficient is on the number of rooms in a house; a standard deviation change in tract mean number of rooms is associated

<sup>19</sup>I used a LASSO regression with 10x crossfold validation to select characteristics, and it retained all of the variables.

<sup>20</sup>As mentioned earlier, neither climate nor electricity emissions factors are impervious to local influence. Urban form can quite meaningfully impact local microclimates through urban heat island effects, but in this paper my measure of climate is at the NOAA climate division level, a geographically coarser definition. And municipal utilities can shape local electricity emissions factors through energy procurement choices but currently make up a small share of overall electricity supply.

with a roughly 7 percent change in tract-level carbon emissions. The remainder of tract effects appear to load primarily onto measures of sprawl, the quality of local bike infrastructure, rurality, density, and household income, with standard deviation changes in these characteristics being associated with a 2–4 percent change in carbon emissions each. It is notable that measures of walkability, transit quality, share of detached homes, and number of cars appear to become less important after conditioning on density, sprawl, and home size. It is possible that this is because these characteristics are very colinear in the observational data; as highlighted earlier, many of these relationships are interconnected.

The Supplemental Appendix shows analogous projections of household fixed effects onto observable neighborhood-level characteristics. I find that correlations between household effects and observable characteristics are about an order of magnitude weaker than those between tract effects and observable characteristics in both the bivariate regressions and the full regression. This is consistent with minimal sorting on unobserved household characteristics that I estimate in KSS. The largest coefficients imply that households with high unobservable potential for carbon emissions sort to tracts where people are on average higher income and have more children, where it is warmer, where electricity is higher-emissions, and where houses are bigger. The Supplemental Appendix presents additional results on the correlates between observable household characteristics and observable place characteristics.

These regressions do not elucidate causal relationships. As is the case with inference about place effects as a bundle, inference about the role of specific amenities from observational data alone is likely to be biased by household sorting. Nevertheless, the observational data suggest features of urban form whose effect on household carbon emissions should be studied further with credible exogenous variation in the amenity itself. Previously, one might worry about whether a setting for such a case study is selected. Can we learn about the effect of lifting zoning restrictions and allowing for smaller lot sizes if people who live in denser cities have significantly different preferences than those who don't? Are improvements to bike infrastructure only effective in cities where a lot of people already bike? The core results of my paper suggest that a meaningful share of variation between places is driven by variation in place effects, with evidence that place effects are constant across heterogeneous populations, mitigating some of these concerns about external validity.

## VI. Implications for Aggregate Carbon Emissions

The wide distribution of place effects suggests that there may be an opportunity to substantially reduce household carbon emissions from residential and transportation energy through what I refer to as place-based climate policies. Place-based climate policies—distinct from regional energy sector regulations or market-based mechanisms designed to encourage decarbonization—aim to reduce household carbon emissions by altering local characteristics that shape household energy choices.<sup>21</sup> They could be implemented at federal or local levels and, building on insights

<sup>21</sup> As transportation and residential sectors electrify and the power grid decarbonizes, the impact of place-based drivers of household emissions will diminish. However, given current challenges in clean electrification, particularly

from labor and urban economics, could be designed to simultaneously reduce carbon emissions and address economic development goals, housing shortages, or local externalities like pollution and congestion.

Infrastructure and local public goods investments make up one category of potential place-based climate policies. The federal government has a history of investing into transportation infrastructure, with the Interstate Highway System being its most notable example (US Department of Transportation 1977). More recently, the Bipartisan Infrastructure Law provided a significant increase to transit funds across the country; the Federal Transit Administration announced in early 2024 that it would be investing \$9.9 billion to support local transit systems in urban areas across the United States (US Department of Transportation 2024). While adding and expanding public transit networks is perhaps the most obvious example of an intervention that might decrease place effects, many cities are implementing less costly initiatives that repurpose existing urban space for community use. Paris's Plan Velo has converted over 200 miles of roads into (often protected) bike lanes as of 2024, with further expansions planned through 2026 (Ville de Paris 2021). Barcelona's Superillas program aims to transform more than half of its car-dominated streets into mixed-use public spaces (Roberts 2019), while New York City's High Line project has repurposed an abandoned elevated railway into a popular pedestrian walkway and park. The COVID-19 pandemic accelerated this trend, sparking "slow" or "open" streets programs that temporarily restricted car traffic to benefit pedestrians and cyclists in many cities of the United States, with some cities now working to make these changes permanent (New York City Department of Transportation 2023; Combs 2020). Expanding the network of electric vehicle chargers is another example of a lower-cost place-based infrastructure investment that can reduce carbon emissions.

A second category of potential place-based policies includes regulatory changes intended to encourage—or remove barriers previously preventing—sustainable urban development. Zoning deregulation, land use reform, and transit-oriented development have all gained traction in the United States in recent years. In 2018, Minneapolis became the first city in the United States to enact a city-wide ban on exclusionary zoning, a common practice across the United States that restricts land to be used for single-family homes only (Mervosh 2018). In 2021, the California State Assembly passed Bills 9 and 10, which streamlined the process of "upzoning" residential land, allowing for the development of up to four units on land previously zoned for single-family homes only and facilitating higher-density construction near transit corridors. This was followed by AB 2097 in 2022, which eliminated most parking minimum requirements for new development (Fulton et al. 2023). At the federal level, President Biden's original infrastructure bill proposal in March 2021 included grants to cities that eliminated exclusionary zoning. While this portion of the bill did not get passed, and many states and municipalities are still debating but not implementing zoning reforms, these examples illustrate the relevance of such approaches in the current policy debate. At the same time, some states and

---

transmission capacity constraints and aging infrastructure (e.g., US Department of Energy 2015), place-based policies that reduce energy demand and alleviate pressure on the electricity grid could be complementary to more traditional decarbonization instruments.

municipalities are making regulatory efforts to make building codes more stringent by, for example, enacting energy efficiency minimum requirements (Levinson 2016) or mandating electrification through natural gas hookup bans (Payne 2021).

This paper does not identify a causal relationship between any specific amenity and place effects, or any specific intervention and place effects, but it shows evidence that low-emissions places are low-emissions not simply due to sorting of low-emissions people to those places, and that low emissions places tend to have amenities that are characteristic of more urban, less sprawling neighborhoods. Using this as motivation, I examine how carbon emissions would change if the national distribution of place effects was more urban than it currently is. Specifically, to approximate a scenario in which the United States limits suburban sprawl and increases the share of households within a region that live in an urban neighborhood, I estimate the effect on emissions if households currently living within a suburban or rural area lived instead in a place with the average place effect of the nearest principal city. A naïve comparison of household emissions shows that, on average, households living in principal cities emit 20 percent less than households living in surrounding areas. After accounting for sorting of households between suburban and urban neighborhoods, my estimates suggest that if every tract had the place effect of the nearest principal city, the emissions of suburban and rural households would decrease by approximately 15 percent.

The majority of principal cities in the United States would not be considered particularly urban on a global scale. To consider the potential effect of deeper urbanization, I examine how household carbon emissions would change if more people lived in places like Manhattan, which is uniquely dense, walkable, and transit oriented within the US context. Specifically, I examine how the emissions of households in the principal cities of the nine largest CBSAs after the New York Metropolitan Area in the United States (US Census Bureau 2024) would change if those cities developed into a place with the average place effect of Manhattan. The observational gap is enormous: Even using large cities as a comparison group, households in Manhattan emit about 73 percent less than observably comparable households in the other 9 large cities. Accounting for unobserved fixed differences between households reduces the gap to 60 percent; people who choose to live in Manhattan are a selected subsample, but their emissions are nevertheless much lower as a result of living in Manhattan than they would be if they lived elsewhere.

These exercises lend insight into how development that shifts population shares across place types by “expanding” places with lower place effects—either by making their neighbors look more like them or by allowing more people to live in such places without changing their fundamentals—could affect emissions in the future. My estimates yield only a first-order, partial equilibrium approximation to the effect of such interventions, as in practice, there would be some re-sorting of populations in response to place-based changes, which would change the distribution of household types living in each place and thereby change aggregate carbon emissions. More importantly, my estimates don’t lend insight into the specific interventions that would result in the largest changes to place effects; this is a critical direction for future research. My results highlight that the potential for urbanization-induced reductions to carbon emissions is overstated when inferred from observational means across places because people choose where to live based in part on their

potential carbon emissions. Nevertheless, because there is substantial variation in household carbon emissions and neighborhood effects explain 15–23 percent of this variation—depending on whether climate and electricity emissions are included in the place effects—my results also imply that even relatively small shifts in the distribution of place effects that households are exposed to could meaningfully decrease aggregate carbon emissions.

## VII. Discussion

This paper is the first to estimate the causal effects of places on household carbon emissions and decompose spatial heterogeneity in carbon emissions into a component driven by these place effects and a component driven by household characteristics and sorting. I find that up to 23 percent of overall heterogeneity in household carbon emissions from residential energy use and commuting across the United States can be explained by neighborhood effects, or roughly 15 percent can be explained by neighborhood effects after accounting for variation driven by climate and electric grid intensity. Paired with high overall heterogeneity, these estimates imply that interventions that change the population-weighted distribution of place effects across the United States, either through direct changes to places or through regulatory changes that make it possible for more people to live in low-emissions places, could result in meaningful reductions in household carbon emissions.

There are several limitations of my empirical analysis that should be taken into consideration while interpreting my results. The first is that due to the survey nature of my data, carbon emissions are noisily measured. This leads to lower explanatory power of the model than is standard in papers using these methods with administrative data to estimate firm wage premia. The relatively low explanatory power of the model could also reflect model misspecification, but with only two observations per household for the majority of my sample, the number of specification tests I can do is limited. Second, there is relatively little variation in urban form and transportation options across the United States; 75 percent of residential land in the United States is zoned for single-family homes only (Badger and Bui 2019), 95 percent of commuters in my sample commute by car, and there is only 1 high-speed rail line in the entire country, which operates at high speed over only roughly 50 miles of track. This is in stark contrast with other parts of the world, where many cities are denser and substantially less car oriented. Moreover, place effects are identified from movers, who differ from the general US population in meaningful ways. Thus, the external validity of my results relies upon estimates being stable to widening the distributions of place and household types.

Establishing that place matters—and how much it matters—for household carbon emissions takes a critical first step toward investigating the welfare impacts of specific place-based climate policies. The welfare effects of a given intervention depend on several parameters whose estimation is outside of the scope of this paper. First, they depend on the causal relationships between local amenities and place effects, and on household preferences for local amenities. While Tiebout (1956) posits that residential sorting allows for efficient provision of local public goods, his framework only applies to amenities without scale economies. Moreover, there is reason to believe that residential sorting is not efficient due to frictions and

exclusionary policies (e.g., Rothstein 2017; Hausman and Stolper 2021; Christensen and Timmins 2023; Avenancio-León and Howard 2022). Estimating causal relationships between local public amenities and household carbon emissions and quantifying whether emissions-relevant local public amenities are at an efficient level are important directions for future work. Second, the welfare impacts of place-based interventions would depend on the costs of implementing them relative to the cost of business as usual or other contender climate policies. Costs can vary dramatically for the same intervention in different settings (Goldwyn et al. 2022), making this estimation difficult, but incorporating cost estimates for a marginal value of public funds analysis (Hendren and Sprung-Keyser 2020) is another important avenue for future research. It is worth emphasizing that because built environment is sticky, infrastructure investments and regulatory choices made in the present day have the potential to increase or decrease the costs of carbon mitigation efforts in the future. Finally, welfare impacts would depend on other externalities or agglomeration benefits of the intervention. For example, the types of interventions highlighted in this paper could also impact local air pollution, congestion, traffic fatalities, and labor market productivity. These co-benefits and harms have been extensively studied in the environmental and urban economics literatures, and estimates could be incorporated into an aggregate welfare effect.
